people to entertain, recognize, and evaluate the differences between true and false beliefs. Given the ever-present menace of enemies within and without, concealment, deception, and the ability to generate false beliefs and recognize them in others would favor survival. But because representations of agency and intention include representations of false belief and deception, human society is forever under threat of moral defection.

If some better ideology is likely to be available somewhere down the line, then, reasoning by backward induction, there is no more justified reason to accept the current ideology than convenience. As it happens, the very same metacognitive aptitude that initiates this problem also provides a resolution through meta-representation of minimally counterintuitive worlds. Invoking supernatural agents who may have true beliefs that people ordinarily lack creates the arational conditions for people to steadfastly commit to one another in a moral order that goes beyond apparent reason and self-conscious interest. In the limiting case, an omniscient and omnipotent agent (e.g., the supreme deity of the Abrahamic religions) can ultimately detect and punish cheaters, defectors,

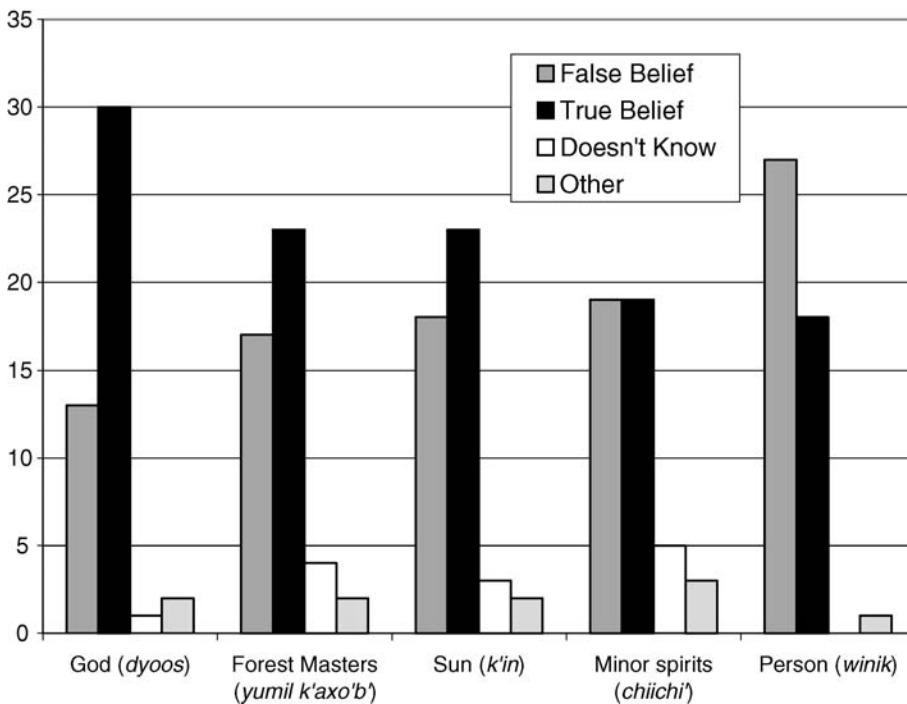

FIGURE 17.4. What's in the container?: Yukatek Maya children's responses to false belief task.

and free riders, no matter how devious (Frank, 1988; Dennett, 1997).

In the competition for moral allegiance, secular ideologies are at a disadvantage. For if people learn that all apparent commitment is self-interested convenience or worse, manipulation for the self-interest of others, then their commitment is debased and withers. Especially in times of vulnerability and stress, social deception and defection in the pursuit of self-preservation are therefore more likely to occur, as Ibn Khaldûn noted long ago (1318/1958, Vol. 2, part III, p. 41). Religion passionately rouses hearts and minds to break out of this viciously rational cycle of self-interest, and to adopt group interests that may benefit individuals in the long run. Commitment to the supernatural underpins the “organic solidarity” (Durkheim, 1912/1995) that makes social life more than simply a contract among calculating individuals. Commitment to the supernatural is further sustained by the relieving of pervasive existential anxieties, to which I now turn.

EXISTENTIAL ANXIETY: AN EXPERIMENT ON WHAT MOTIVATES RELIGIOUS BELIEF

If supernatural agents are cognitively salient and possess hidden knowledge and powers, then they can be invoked to ease existential anxieties, such as death and deception, that forever threaten human life everywhere. To test this, Norenzayan, Hansen, and Atran (reported in Atran & Norenzayan, 2004; Norenzayan & Hansen, 2006) built on a study by Cahill, Prins, Weber, and McGaugh (1994) dealing with the effects of adrenaline (adrenergic activation) on memory.

The hypothesis was that existential anxieties (particularly death) deeply affect not only how people remember events but also their propensity to interpret events in terms of supernatural agency. Each of three groups of college students was primed with one of three different stories (Table 17.2): Cahill et al.’s (1994) uneventful story (neutral prime), their stressful story (death prime), and another uneventful story whose event-structure matched the other two stories but included a prayer scene (religious prime). Afterwards, each group of subjects read a *New York Times* article (October 2, 2001) whose lead-in ran: “Researchers at Columbia University, expressing surprise at their own findings, are reporting that women at an

in vitro fertilization clinic in Korea had a higher pregnancy rate when, unknown to the patients, total strangers were asked to pray for their success.” The article was provided under the guise of being a story about “media portrayals of scientific studies.” Finally, students rated strength of their belief in God and the power of supernatural intervention (prayer) on a 9-point scale.

Results show that strength of belief in God’s existence and in the efficacy of supernatural intervention (Figure 17.5) are reliably stronger after exposure to the death prime than to either to the neutral or religious prime (no significant differences between either uneventful story). This effect held even after controlling for religious background and prior degree of religious identification. In a cross-cultural follow-up, 75 Yukatek-speaking Maya villagers were tested with stories matched for event structure but modified to fit Maya cultural circumstances. They were also asked to recall the priming events. We (Atran & Norenzayan, 2004) found no differences among primes for belief in the existence of God and spirits (near the ceiling in this very religious society). However, subjects’ belief in efficacy of prayer for invoking the deities was significantly greater with the death prime than with religious or neutral primes. Awareness of death more strongly motivates religiosity than mere exposure to emotionally nonstressful religious scenes, such as praying. This supports the claim that emotionally eruptive existential anxieties motivate supernatural beliefs.¹⁶

According to terror management theory (TMT), cultural worldview is a principal buffer against the terror of death. TMT experiments show that thoughts of death function to get people to reinforce their cultural (including religious) worldview and derogate alien worldviews (Greenberg et al., 1990; Pyszczynski et al., 1999). In this view, then, awareness of death should enhance belief in a worldview-consistent deity but diminish belief in a worldview-threatening deity. An alternative view is that the need for belief in supernatural agency overrides worldview defense needs for death-aware subjects.

To test these competing views, Norenzayan, Hansen, and Atran (reported in Atran & Norenzayan, 2004) told 73 American undergraduates that the prayer groups described in the first experiment described earlier were Buddhists in Taiwan, Korea, and Japan. Supernatu-

TABLE 17.2. Three Stories with Matching Events Used to Prime Feelings of Religiosity: Neutral (Uneventful), Death (Stressful), Religious (Prayer Scene)

Neutral	Death	Religious
1 A mother and her son are leaving home in the morning.	A mother and her son are leaving home in the morning.	A mother and her son are leaving home in the morning.
2 She is taking him to visit his father's workplace.	She is taking him to visit his father's workplace.	She is taking him to visit his father's workplace.
3 The father is a laboratory technician at Victory Memorial Hospital.	The father is a laboratory technician at Victory Memorial Hospital.	The father is a laboratory technician at Victory Memorial Hospital.
4 They check before crossing a busy road.	They check before crossing a busy road.	They check before crossing a busy road.
5 While walking along, the boy sees some wrecked cars in a junkyard, which he finds interesting.	While crossing the road, the boy is caught in a terrible accident, which critically injures him.	While walking along, the boy sees a well-dressed man stop by a homeless woman, falling on his knees before her, weeping.
6 At the hospital, the staff are preparing for a practice disaster drill, which the boy will watch.	At the hospital, the staff prepare the emergency room, to which the boy is rushed.	At the hospital, the boy's father shows him around his lab. The boy listens politely, but his thoughts are elsewhere.
7 An image from a brain scan machine used in the drill attracts the boy's interest.	An image from a brain scan machine used in a trauma situation shows severe bleeding in the boy's brain.	An image from a brain scan that he sees reminds him of something in the homeless woman's face.
8 All morning long, a surgical team practices the disaster drill procedures.	All morning long, a surgical team struggles to save the boy's life.	On his way around the hospital, the boy glances into the hospital's chapel, where he sees the well-dressed man sitting alone.
9 Makeup artists are able to create realistic-looking injuries on actors for the drill.	Specialized surgeons are able to reattach the boy's severed feet, but can not stop his internal hemorrhaging.	With elbows on his knees, and his head in his hands, the man moves his lips silently. The boy wants to sit beside him, but his father leads him away.
10 After the drill, while the father watches the boy, the mother leaves to phone her other child's preschool.	After the surgery, while the father stays by the dead boy, the mother leaves to phone her other child's preschool.	After a brief tour of the hospital, while the father watches the boy, the mother leaves to phone her other child's preschool.
11 Running a little late, she phones the preschool to tell them she will soon pick up her child.	Barely able to talk, she phones the preschool to tell them she will soon pick up her child.	Running a little late, she phones the preschool to tell them she will soon pick up her child.
12 Heading to pick up her child, she hails a taxi at the number nine bus stop.	Heading to pick up her child, she hails a taxi at the number nine bus stop.	Heading to pick up her child, she hails a taxi at the number nine bus stop.

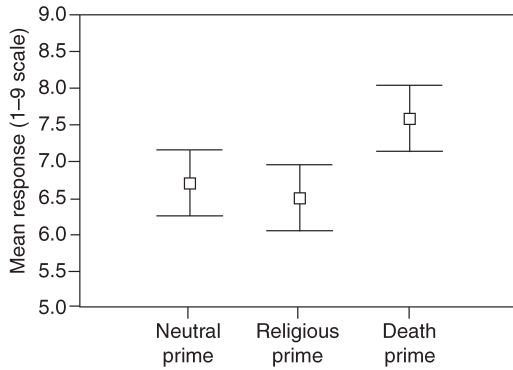

FIGURE 17.5. Strength of belief in supernatural power after priming (neutral, religious, or death), then reading a newspaper article about effects of prayer on pregnancy. Vertical bars represent margin of error at $p = .05$.

ral belief was measured either shortly after the primes or after a significant delay between the primes and the belief measures. When the primes were recently activated, as expected, there was a stronger belief in the power of Buddhist prayer in the death prime than in the control prime. Remarkably, death-primed subjects who previously self-identified as strong believers in Christianity were *more* likely to believe in the power of Buddhist prayer. In the neutral (control) condition, there was no correlation between Christian identification and belief in Buddhist prayer. Given a choice between supernatural belief versus rejecting an alien worldview (Buddhism), Christians chose the former. This finding is difficult to explain simply in terms of bolstering a cultural (in this case, Christian-centered) worldview.¹⁷

There was no evidence for differences in recall of priming events after subjects rated their strength of belief in God and the efficacy of supernatural intervention. With this in mind, note that uncontrollable arousal mediated by adrenergic activation (e.g., subjects chronically exposed to death scenes) can lead to posttraumatic stress disorder if there is no lessening of terror and arousal within hours; however, adrenergic blockers (e.g., propranolol, guanfacine, and possibly antidepressants) can interrupt neuronal imprinting for long-term symptoms, as can cognitive-behavioral therapy (work by Charles Marmar, discussed in McReady, 2002, p. 9). A plausible hypothesis is that heightened expression of religiosity fol-

lowing exposure to death scenes that provoke existential anxieties may also serve this blocking function. The further claim—that not only do existential anxieties spur supernatural belief but also these beliefs are in turn affectively validated by assuaging the very emotions that motivate belief in the supernatural—has yet to be tested.

SACRED VALUES IN DECISION MAKING AND THE LIMITS OF RATIONAL CHOICE

Religious behavior often seems to be motivated by *sacred values* (SVs). A sacred value incorporates moral and ethical beliefs and “independently of its prospect of success.” Max Weber (1978, Vol. 1, p. 24) distinguishes the non-instrumental “value rationality” of religions and transcendent political ideologies from the “instrumental rationality” of *realpolitik* and the marketplace. Instrumental rationality involves strict cost-benefit calculations regarding goals, and entails abandoning or adjusting goals if costs for realizing them are too high. For Immanuel Kant (1788/1997), virtuous religious behavior is its own reward, and attempts to base it on utility nullifies its moral worth.

High-cost personal sacrifices to (nonkin) others in society seem to be typically motivated by, and framed in terms of, noninstrumental values. This includes Jihadist conceptions of martyrdom, which also involve a moral commitment to kill infidels for the sake of God. One review indicated that “only a minority of human violence can be understood as rational, instrumental behavior aimed at securing or protecting material rewards” (Baumeister, Smart, & Boden, 1996, p. 5). Historically, religiously motivated violence tends to underpin the most intractable and enduring conflicts within and between cultures (Allport, 1956) and civilizations (Huntington, 1997).

Political scientists and economists acknowledge the role of religious values in coordinating groups for economic, social, and political activities, and in providing people with immunity that goes with action in large numbers (Schelling, 1963). From a rational-choice perspective, such values operate instrumentally to form convergent trust among masses of people with disparate interests and preferences (Hardin, 1995), thus reducing “transaction

costs” that would otherwise be needed to mobilize them (Fukuyama, 1995). Others (Horowitz, 1984; Varshney, 2003) grant the instrumental value of “ethnicity”—and values rooted in other ascriptive (birth-based) identities such as religion and language—but ask: “Why would ethnicity be the basis for mobilization at all?” And why does the mobilization of these values energize the most enduring and intractable conflicts between groups (Cohen, 2002)? This suggests that noninstrumental values possess inherent qualities that instrumental values may lack (passion, obligation), and that these two sorts of values can interact in intricate ways. (Of course, one can always recast noninstrumental values in instrumental terms, just as one can always frame any perceptual or conceptual relationship in terms of “similarity”; but the issue is whether doing so helps or hinders explanatory power to predict further judgments and decisions.)

Psychologists have recently developed controlled ways of testing ideas about allied notions of “protected values” and “taboo trade-offs” (Fiske & Tetlock, 1997). Tetlock (2000) described a protected value as “any value that a moral community implicitly or explicitly treats as possessing infinite or transcendental significance that precludes comparisons, trade-offs . . . with bounded or secular values.” Despite more than a decade of research on protected values and decision making, knowledge of their influence is quite limited. What is clear is that protected values have a privileged link to moral outrage and other emotions (Baron & Spranca, 1997), especially when a person holding a sacred value is offered a secular value or trade-off, such as selling one’s child or selling futures betting on acts of terrorism (Medin, Schwartz, Blok, & Birnbaum, 1999, Tetlock, 2003).

One claim is that SVs are associated with deontological, or moral obligation, requirements rather than consequentialist rules that strictly weigh benefits against costs or link means to ends. People with SVs often say that one has a moral obligation to act, independent of likelihood of success, “because I couldn’t live with myself if I didn’t.” But there is little analysis of the mental accounting involved in quantity insensitivity (cf. Baron & Greene, 1996) or of the stability of values across decision frames (Fischhoff et al., 1980): For example, a medical decision framed as one of sur-

vival may be insensitive to cost, but not when couched in terms of a marginal increase in prospects for survival (Tversky, Slovic, & Sattath, 1988). Tanner and Medin (2004) find protected values to be associated with elimination of otherwise robust framing effects, such as favoring choices framed as gains over those framed as losses. Beyond this, there is little consensus. Moreover, analyses that have been done are primarily with “standard” laboratory populations of university students, using fictional scenarios—a practice that sometimes produces results that do not readily generalize to other populations and methods (Medin & Atran, 2004; cf. Henrich et al., 2001).

Some tentative studies couple world events and people with SVs who engage in heroism or suicide terrorism to underline the importance of morally motivated decision making (Atran, 2004; Skitka & Mullen, 2002). But significant empirical and theoretical challenges remain. For example, researchers note (Baron & Spranca, 1997; Tetlock, 2003) that although people who ostensibly hold SVs sometimes seem to treat them as having infinite utility (e.g., in refusing to consider trade-offs), this implies that people with such values should spend literally all their time and effort protecting and promoting that value. Moreover, infinite utility is incompatible with any sort of “preference schedule”: Expected utilities are weighted averages, which makes little sense when one of the terms is infinite.

Thus some have suggested these values are only pseudosacred (Baron & Leshner, 2000; Thompson & Gonzalez, 1997); others have noted that people with SVs may nonetheless engage in indirect trade-offs (McGraw & Tetlock, 2005; Tetlock, 2000). One may be tempted to think of sacred values as self-serving “posturing,” but the reality of acts such as suicide bombings and a monk’s self-immolation undermines this stance (Gambetta, 2005). Moreover, SVs necessary to an individual’s identity may take on truly absolute value only when value-related identity seems gravely threatened (e.g., via humiliation), just as food may take on absolute value only when sustenance for life is threatened.

For example, our research team (Atran, 2006a; Ginges, Atran, Medin, & Shikaki, in press) recently conducted studies indicating that instrumental approaches to resolving political disputes are suboptimal when protago-

nists transform the issues or resources under dispute into essential moral values, that is, values that a moral community treats as possessing transcendental significance that precludes comparisons or tradeoffs with instrumental values of realpolitik or the marketplace. Instrumental decision making involves strict cost-benefit calculations regarding goals and entails abandoning or adjusting goals if costs of realizing them are too high. We found that emotional outrage and support for violent opposition to compromise over sacred values is (1) not mitigated by offering instrumental incentives to compromise but (2) is decreased when the adversary makes instrumentally irrelevant compromises of their own sacred values.

In a survey of Jewish Israelis living in the West Bank and Gaza (settlers, $N = 601$) conducted in August 2005, days before Israel's withdrawal from Gaza, we randomly presented participants with one of several hypothetical peace deals. All involved Israeli withdrawal from 99% of the West Bank and Gaza in exchange for peace. We identified a subset of participants (46%) who had transformed land into an essential value; they believed that it was never permissible for the Jewish people to "give up" part of the "Land of Israel," no matter how extreme the circumstance. For these participants, all deals thus involved a "taboo" trade-off. Some deals involved an added instrumental incentive, such as money or the promise of a life free of violence (taboo+), while in other deals Palestinians also made a "taboo" trade-off over one of their own sacred values in a manner that neither added instrumental value to Israel nor detracted from the taboo nature of the deal being considered ("tragic"). From a rational perspective, the taboo+ deal is improved relative to the taboo deal and thus violent opposition to the tragic deal should be weaker. However, we observed the following order of support for violence: taboo+ > taboo > tragic (see Figure 17.6A), where those evaluating the tragic deal showed less support for violent opposition than the other two conditions. An analysis of intensity of emotional outrage again found that taboo+ > taboo > tragic (see Figure 17.6C); those evaluating the tragic deal were least likely to report anger or disgust at the prospect of the deal being signed.

These results were replicated in a survey of Palestinian refugees ($N = 535$) in Gaza and the West Bank conducted in late December 2005, 1

month before Hamas was elected to power. In this experiment, hypothetical peace deals (see supporting online materials) all violated the Palestinian "right of return," a key issue in the conflict (Shamir & Shikaki, 2005). For the 80% of participants who believed this was an essential value, we once more observed that for violent opposition the order between conditions was taboo+ > taboo > tragic, where those evaluating a "tragic" deal showed lowest support for violent opposition (see Figure 17.6B). Further, the same order was found for two measures ostensibly unrelated to the experiment: (1) the belief that Islam condones suicide attacks, and (2) reports of joy at hearing of a suicide attack (see de Quervain et al., 2004, for evidence of joy as a neurophysiological correlate of revenge). Compared to refugees who had earlier evaluated a taboo or taboo+ deal, those who had evaluated a tragic deal believed less that Islam condoned suicide attacks and were less likely to report feeling joy at hearing of a suicide attack (see Figure 17.6D). In neither the settler nor the refugee studies did participants responding to the "tragic" deals regard these deals as more implementable than participants evaluating taboo or taboo+ deals.

These experiments reveal that in political disputes where sources of conflict are cultural, such as the Israeli-Palestinian conflict or emerging clashes between the Muslim and Judeo-Christian world, violent opposition to compromise solutions may be exacerbated rather than decreased by insisting on instrumentally driven tradeoffs, while noninstrumental symbolic compromises may reduce support for violence.¹⁸

Or consider religiously motivated terrorism. Most terrorists who have been studied—including would-be or captured suicide bombers—fail to show any psychopathology or sociopathy, and are generally at least as educated and economically well-off as their surrounding populations (Krueger & Maleckova, 2003; Atran, 2003; Stern, 2003; Sageman, 2004; Merari, 2005). Such findings are often taken to support the idea that terrorist action—including self-destruction—derives from rational decisions to optimize strategies for attaining sociopolitical goals (Pape, 2005; Madsen, 2004; M. Bloom, 2005): the religious "bargain" of mostly young men dying for a promising afterlife (Stark, 2000); ultimate sacrifice as maximizing the goal of improving lives of fam-

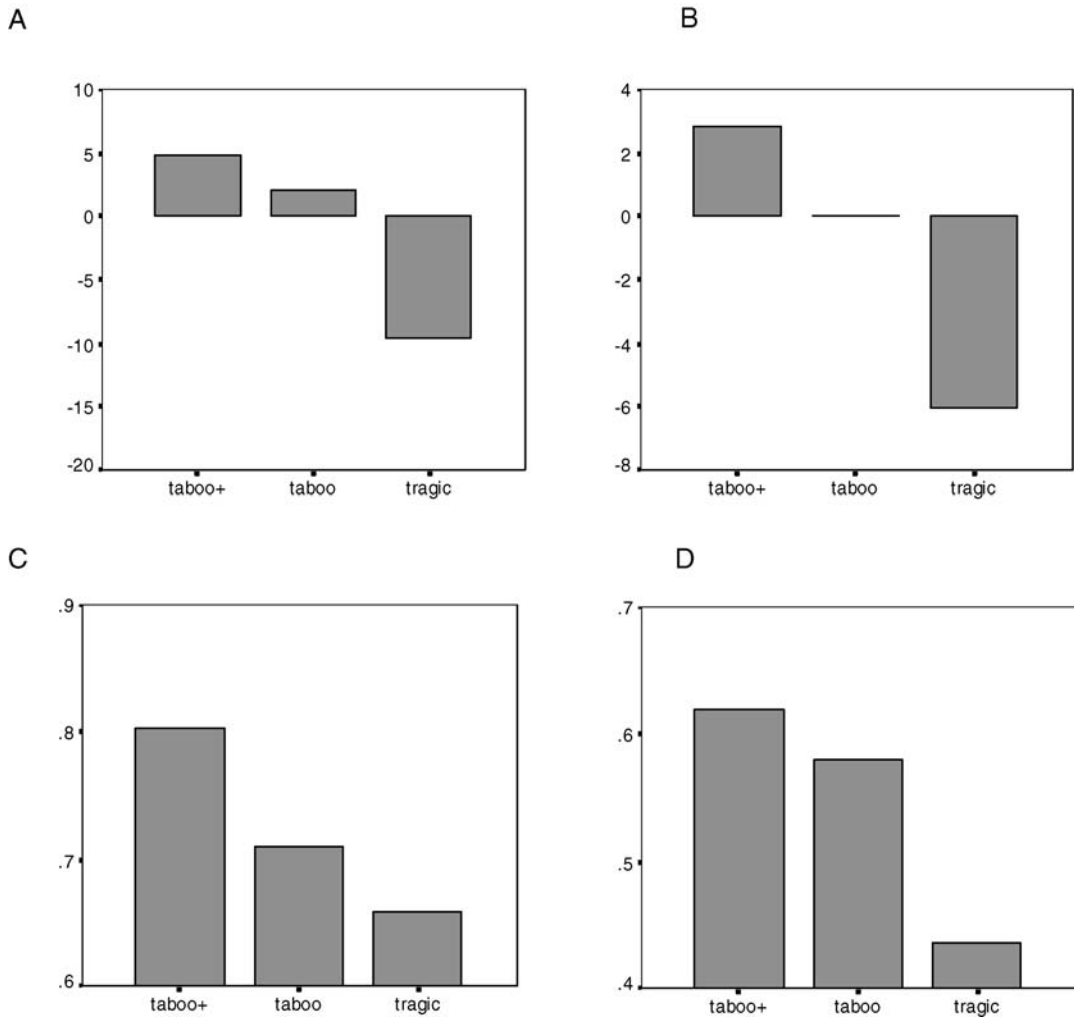

FIGURE 17.6. Predictions of the percentage of the population who would use violence to oppose: a peace deal perceived to violate a sacred value (taboo condition); the taboo deal plus an added instrumental incentive (taboo+); or the taboo deal plus a sacred value concession without instrumental value, from the adversary (tragic) for (A) Israeli settlers (linear trend $F[1,195] = 5.698, P = .018$) and (B) Palestinian refugees ($F[1, 384] = 7.201, P = .008$). Parallel results obtained for emotional reactions by: (C) settlers reporting anger or disgust at an Israeli leader who would agree to the tradeoff being evaluated ($F[1, 260] = 4.436, P = .036$); and (D) refugees reporting “joy” at hearing of a suicide bombing according to the type of tradeoff being evaluated ($F[1, 418] = 7.48, P = .007$). The trend of emotional intensity and support for violence in each case, $\text{taboo+} > \text{taboo} > \text{tragic}$, could not be predicted by an instrumental account of human behavior.

ily or compatriots, which offsets the “opportunity cost” of an educated life lost prematurely (Azzam, 2005; cf. Becker, 1968); and “trading life” for a social identity that is affirmed in death but devalued by continued living (Harrison, 2006; cf. Akerlof & Kranton, 2000).

These speculations are theoretically plausible; however, no empirical study involving structured interviews or experiments with religious suicide terrorists has ever put these speculations to empirical test. Rather than obey a utilitarian “logic of rational consequence,” these actors perhaps more closely follow a “logic of moral appropriateness” (Hoffman & McCormick, 2004). For example, I recently interviewed 12 self-identified recruits for martyr attack from the Hamas Block at al-Najah University in Nablus (which provides more suicide bombers than any other demographic group of Palestinians) and six members each of Hamas and Al Aqsa’ Martyrs Brigades in Gaza’s Jabaliyah refugee camp. All were asked questions of the sort, “So what if your family were to be killed in retaliation for your action?” or “What if your father were dying and your mother found out your plans for a martyrdom attack and asked you to delay until the family could get back on its feet?” To a person they answer along lines that there is duty to family but duty to God cannot be postponed. But most of those interviewed also say that if a roadside bomb can produce the same damage (i.e., without causing the deaths of any members of the group), then it is preferable. More recent interviews with leaders and foot soldiers of Indonesia’s Jemaah Islamiyah, Al-Qaeda’s mainly ally in Southeast Asia, show similar results (cf. Atran & Stern, 2005; Atran, 2006b).¹⁹ In short, when the focus is on the act itself, they may be even anti consequentialist, but when the focus is on the enemy, consequentialism emerges.

In summary, whereas study of judgment and decision making has greatly advanced (for reviews, see Kahneman, 2003; Markman & Medin, 2002; Schneider & Shanteau, 2003), much more is known about decision-making facets of economic behavior than about morally motivated behavior, especially religiously motivated social and political behavior. I hope this will change given the critical importance of religious values in human judgment and decision making, and their crucial involvement in personal well-being, cultural survival, and political conflict.

CONCLUSION: EVOLUTION’S CANALIZING LANDSCAPE

Think metaphorically of humankind’s evolutionary history as a landscape formed by different mountain ridges. This landscape functions everywhere to canalize, but not determine, individual and cultural development. It greatly reduces the possible sources of religious expression into structures that constantly reappear across history and societies.

This landscape is shaped by natural selection. It is ancestrally defined by specific sets of affective, social, and cognitive features—different mountain ridges. Each ridge has a distinct contour, with various peaks whose heights reflect evolutionary time. One such evolutionary ridge encompasses panhuman emotional faculties, or “affect programs.” Some of these affect programs, such as surprise and fear, date at least to the emergence of reptiles. Others, such as grief and guilt, may be unique to humans. Another ridge includes social interaction schemas. Some schemas may go far back in evolutionary time, such as those involved in detecting predators and seeking protectors, or which govern direct “tit-for-tat” reciprocity (“You scratch my back, I’ll scratch yours”). Other social interaction schemas seem unique to humans, such as committing to nonkin. Still another ridge encompasses panhuman mental faculties, or cognitive “modules,” such as folkmechanics, folkbiology, and folkpsychology. Folkmechanics is this ridge’s oldest part, with links to amphibian brains. Folkpsychology is the newest, foreshadowed among apes. Only humans appear to metarepresent multiple models of other minds and worlds (Tomasello, Kruger, & Ratner, 1993), including the supernatural.

Human experience lies along this evolutionary landscape, usually converging on more or less the same life paths—much as rain that falls anywhere in a mountain valley landscape drains into a limited set of lakes or rivers (Kauffman, 1993; Sperber, 1996). As humans randomly interact and “walk” through this landscape, they naturally tend toward certain forms of cultural life, including religious paths. Cultures and religions do not exist apart from the individual minds that constitute them and the environments that constrain them, any more than a physical path exists apart from the organisms that tread and groove it, and the surrounding ecology that restricts its location and

course. Individual minds mutually interact within this converging landscape in an open-ended time horizon, exploiting its features in distinctive ways to produce the religious and cultural diversity we see in the world and throughout human history.²⁰

Nevertheless, all religions follow the same structural contours. They invoke supernatural agents to deal with emotionally eruptive existential anxieties, such as loneliness, calamity, and death. They have malevolent and predatory deities, as well as more benevolent and protective ones. These systematically, but minimally, violate modularized expectations about folkmechanics, folkbiology, and folkpsychology. And religions communally validate counterintuitive beliefs through musical rituals and other rhythmic coordinations of affective body states. Finally, these landscape features are mutually constraining. They include evolved constraints on emotional feelings and displays, modularized conceptual and mnemonic processing, and social commitments that attend to information about cooperators, protectors, predators, and prey. Religious and cultural life is pervaded and largely constituted by the manipulation of these landscape features—for good or bad.

ACKNOWLEDGMENTS

Thanks to Richard Sosis for the material in the section “adaptationist Theories of Religion” (apart from “Other Functionalist Accounts”); Ara Norenzayan for contributions to the sections “Cultural Survival” and “Existential Anxiety” and for Figures 17.1 and 17.5; Harvey Whitehouse for information in the section “Modes of Religiosity” and for Figures 17.2 and 17.3; Nicola Knight and Paulo Sousa for analyses in the section “Metarepresenting Counterintuitive Worlds” and for Figure 17.4; and Jeremy Ginges and Douglas Medin for ideas and insights in the section “Sacred Values in Decision Making.” My appreciation also to the National Science Foundation for research support on some of the issues discussed in this chapter (Grant Nos. SBR 9707761, SBR 0132469, SBR 0424629, BCS-0446738, and SBE-0527396).

NOTES

1. No conceptual distinction is made here between “culture” and “society” or “mind” and “brain.”

2. In a survey of persons who reported a religious experience (Greeley, 1975), music emerges as the single

most important elicitor of the experience. Listeners as young as 3 years old reliably associate basic or primary emotions to musical structures, such as happiness, sadness, fear and anger (Trainor & Trehub, 1992; Panksepp, 1993).

3. According to the European Interactive Advertising Association, the Internet increasingly represents the essential media for the 15–24 age group, which is “the holy grail” for most advertisers: “European Youth Ditching TV and Radio for Web,” *European Tech Wire* (retrieved June 24, 2005, from www.europeantechwire.com/etw/2005/06/24/). Personal bonds formed online without physical contact appear to generate solid reputations for trustworthiness and the same deep commitment generated by physical intimacy, but often faster and over a wider set of personal relations (Resnick & Zeckhauser, 2002). A recent study of online dating by researchers at the University of Bath indicates that the Internet allows men to manifest emotions that cement durable relationships in ways that are easier than face-to-face contact: “Internet Dating Much More Successful Than Thought,” online press release, University of Bath, February 2005 (www.eurekaalert.org/pub_releases/2005-02/uob-idm021305.php). The Web also lets women enter into chat rooms with men who would otherwise shun female contact, and it empowers a minority of two in dialogue with the sentiment that they can span the world.

4. Although calculations of economic or political utility often influence religious practices (Stark, 2000), religious sacrifice usually costs something for the persons on whose behalf the offering is made. That is why “sacrifice of wild animals which can be regarded as the free gift of nature is rarely allowable or efficient” (Robertson Smith, 1894, p. 466). Thus, for the Nuer of Sudan, substituting a highly valued item (cow) by one less-valued (fowl or vegetable) is allowable only to a point, after which “a religious accounting might reveal that the spirits and ghosts were expecting a long overdue proper sacrifice, because accounts were out of balance so to speak” (Evans-Pritchard, 1940, p. 26). In many cases, the first or best products of one’s livelihood goes to the gods, as with the first fruits of the Hebrews or the most perfect maize kernels of the Maya. Most, if not all, societies specify obligatory circumstances under which religious sacrifice must be performed, regardless of economics.

5. As Dan Sperber (1996) asked in an open communication to the Evolution and Human Behavior Society: “Is fitness a matter of having descendants with a recognizable ideology? Of population size? Of variations in size (expansion)? Of duration? Of some weighted combination of size and duration? What of social systems that expand rapidly at the expense of heritability (empires)?” Without answers to such questions (and none seem forthcoming) the idea of societal-level fitness is hopelessly vague.

6. In a student project in Michigan, Sara Konrath compared interpretations of cultural sayings (e.g., “Let a thousand flowers bloom”) among 26 control subjects

and 32 subjects with autism. Subjects with autism were significantly more likely to paraphrase closely and repeat content from the original statement (e.g., “Don’t cut flowers before they bloom”). Controls were more likely to infer a wider range of cultural meanings, with little replicated content (e.g., “Go with the flow,” “Everyone should have equal opportunity”)—a finding consistent with previous results from East Asians (who were familiar with “Let a thousand flowers bloom” as Mao’s credo; Atran 2001). Only subjects with autism, who lack inferential capacity normally associated with theory of mind (ToM), came close to being “meme machines.” They may be excellent replicators of literal meaning, but they are poor transmitters of cultural meaning. (To deal with deficits in counterfactual thinking, St. Paul’s Church in Alabama [Trenton Diocese] has a special program for people with autism: “The church requires that children who receive Holy Communion be able to recognize the difference between ordinary bread and the Eucharist. . . . The St. Paul’s program was designed to teach the difference” (Rev. Sam Sirianni, cited in A. Raboteau, “Celebrating a Milestone,” *Austism Society of Alabama, National and World New Forum*, retrieved June 25, 2000, from www.autism-alabama.org/ubb/Forum2/html/000145.html). With some exceptions, ideas do not reproduce or replicate in minds in the same way that genes replicate in DNA. They do not generally spread from mind to mind by imitation. It is biologically prepared, culturally enhanced, richly structured minds that generate and transform recurrent convergent ideas from often fragmentary and highly variable input (Sperber & Hirschfeld, 2004; Atran, Medin, & Ross, 2005).

7. Although the Buddha and the buddhas are not regarded as gods, Buddhists clearly conceive of them as “counterintuitive agents” (Pyysiäinen, 2003). In Sri Lanka, Sinhalese relics of the Buddha have miraculous powers. In India, China, Japan, Thailand, and Vietnam, magic mountains and forests are associated with the Buddha; literature and folklore in every Buddhist tradition recount amazing events surrounding the Buddha and the buddhas.

8. Experiments with adults in the United States (J. Barrett & Keil, 1996) and India (J. Barrett, 1998) further illustrate the gap between theological doctrine and actual psychological processing of religious concepts. When asked to describe their deities, subjects in both cultures produced abstract and consensual theological descriptions of gods as being able to do anything, to anticipate and react to everything at once, always to know the right thing to do, and to be able to dispense entirely with perceptual information and calculation. When asked to respond to narratives about these same gods, the same subjects described the deities as being in only one place at a time, puzzling over alternative courses of action, and looking for evidence in order to decide what to do (e.g., to save Johnny first, who’s praying for help because his foot is stuck in a river in the United States and the water is rapidly rising, or to save little Mary

first, whom He has seen fall on railroad tracks in Australia where a train is fast approaching).

9. An example from ethology offers a parallel. Many bird species have nests parasitized by other species. Thus, the cuckoo deposits eggs in passerine nests, tricking the foster parents into incubating and feeding the cuckoo’s young. Nestling European cuckoos often dwarf their host parents (Hamilton & Orrians, 1965): “The young cuckoo, with its huge gape and loud begging call, has evidently evolved in exaggerated form the stimuli which elicit the feeding response of parent passerine birds. . . . This, like lipstick in the courtship of mankind, demonstrates successful exploitation by means of a ‘super-stimulus’ ” (Lack, 1968). Late nestling cuckoos have evolved perceptible signals to *manipulate* the passerine nervous system by initiating and then arresting or interrupting normal processing. In this way, cuckoos are able to subvert and to co-opt the passerine’s modularized survival mechanisms.

10. For Aristotle, the world that could be properly described in ordinary Greek was the world that is (nomologically). This led him to conflate the world’s ontological structure (what philosophy and science consider to be the ultimate “stuff” composing the world) with the semantic structure of language (the constraints governing the ordinary relations between words and thoughts). More recent philosophers interpret the notion of a category mistake to be a logical or semantic “type confusion” (Sommers, 1963; Pap, 1963).

11. According to Boyer (1994, 2000), bodiless supernaturals are counterintuitive because they think and act but lack physical substance. The matter is not so simple. First, experiments with infants and adults indicate that ordinary intuitions about causal agents do not require knowledge or perception of material substance, only the expectation (perhaps never actually realized) that there *ultimately is* a physical source of intentional action (Csibra et al., 1999). Ontological violations block such expectations being realized *even in principle* (e.g., invisible agents versus heard but unseen beings). They countermand rules for eventual processing, not actual perception. Second, not all mental states are equally bound to ordinary intuitions about bodies. Recent studies with American school children indicate that children from five years on more readily attribute epistemic mental states (see, think, know) to beings in the afterlife than psychobiological mental states (hunger, thirst, sleepiness; Bering & Bjorklund, 2002). Ordinary distinctions between mind and body (e.g., dreaming) thus seem to provide at least *some* intuitive support for extraordinary beings with disembodied minds (Hobbes, 1651/1901).

12. J. Barrett and Nyhoff (2001, p. 79) list as common items “a being that can see or hear things that are not too far away”; “a species that will die if it doesn’t get enough nourishment or if it is severely damaged”; “an object that is easy to see under normal lighting conditions.” Such items fall so far below ordinary expectations that communication should carry some new or sa-

lient information that J. Barrett and Nyhoff (2001, pp. 82–83) report: “common items were remembered so poorly relative to other items. . . . In some instances of retelling these items, participants tried to make the common property sound exciting or unusual.” In other words, some subjects tried to meet minimum conditions of relevance (Sperber & Wilson, 1995). For the most part, common items failed these minimum standards for successful communication.

13. Maximally counterintuitive statements (MXCI) were created by modifying a concept with two properties taken from another ontological category (e.g., squinting wilting brick). To control for memory differences on two versus three-word items, for each MXCI statement, a matching statement was generated, with only one of the properties being counterintuitive (e.g., chattering climbing pig).

14. Psychologists familiar with Tulving's (1972) original semantic–episodic distinction may find this confusing, because both types of memory were supposed to be verbal and propositional. According to Whitehouse, highly infrequent episodes seem to be engraved in detail in participants' minds, confidently and forever, as especially vivid “flashbulb memories” (Brown & Kullick, 1982) akin to the memories of Americans who experienced such personally momentous social events as, the Kennedy assassinations, the explosion of the Challenger Space Shuttle, or 9/11 (though it is not clear that the psychologist's notion of flashbulb memory is entirely appropriate inasmuch as many so-called flashbulb memories seem to endure and stabilize more through narrative consolidation, including via “TV priority,” rather than relived emotion; Neisser & Harsch, 1992).

15. Figure 17.3 indicates that emotionally arousing and unusual experiences, or “rites of terror,” will lead to idiosyncratic beliefs or a “lack of uniformity.” Shinobu Kitayama (personal communication) suggests an alternate hypothesis: For these highly arousing, ambiguous experiences, people will rely on culturally supplied explanations and narratives to make sense of their “once in a lifetime” experiences. If that were so, highly imagistic, arousing, unusual, or ambiguous experiences may lead to uniformity within a culture, because people would rely on common culturally supplied narratives to make sense of the event. This may be true of revival meetings. In any event more work is needed.

16. In control conditions, equally anxiety-provoking scenarios (e.g., a visit to the dentist, where dental pain is experienced) did not lead to stronger supernatural belief. Moreover, whenever stronger anxiety was found in the mortality salience condition, controlling for self-reported anxiety (measured on the PANAS scale) failed to eliminate the effect (Norenzayan & Hansen, 2006).

17. One interpretation is that if supernatural intervention works for Buddhism, this would confirm the feasibility of a similar intervention by a Christian god. But further experiments by Hansen and Norenzayan provide compelling evidence that (1) Christians are un-

willing to believe in Buddha or shamanic spirits in control conditions, and they believe in God far more than they believe in Buddha or spirits and (2) Christian subjects shift toward more belief in Buddha and spirits under mortality salience. Moreover, identification with Christian faith is uncorrelated with belief in Buddha and spirits in control conditions, but *positively* correlated under mortality salience. One possibility that is not ruled out by these experiments is that Christians may believe that if Buddha or shamanic spirits exist, so does God or Jesus. This interpretation is not that different from what we suggest, namely, that people are generally open to the supernatural, no matter who the deity is, under mortality salience. It is clear that people are *not* derogating culturally other deities. This contrasts markedly with TMT claims that, under mortality salience, people derogate other cultures.

18. One alternative interpretation of the data is to argue that the Palestinians' “sacred value” trade-offs in the tragic condition signaled greater willingness to compromise on their part. If that were the case, the “tragic” condition might be superior *instrumentally* to the other two conditions, because participants could find it easier to believe that the deal would be peacefully and successfully implemented. To test this interpretation, participants were asked whether they believed that the deal they had been presented with would be “peacefully and successfully implemented.” Responses were scored 1 for *yes*, .5 for *not sure*, and 0 for *no*. The data showed that this alternative interpretation did not hold.

19. For a sample set of questions and responses, see S. Atran, “The Emir: An interview with the Abu Bakr Ba'asyir, alleged leader of *Jemaah Islamiyah*,” *Spotlight on Terrorism* (Jamestown Foundation), September 15, 2005; available at jamestown.org/terrorism/news/article.php?articleid=2369782.

20. The working notion of “religion” used here—a group's costly commitment to a counterintuitive world of supernatural beings who manage people's existential anxieties—is not meant to *define* religion or to delimit its natural scope and limits. It is used only to circumscribe roughly what people would ordinarily include the term. As with Darwin's use of the commonsense notion of species, which first focused his attention, subsequent discoveries revealed only rough correspondence between the commonsense construct (species) and historically contingent patterns of evolution (more or less geographically isolated and interbreeding populations). Darwin continued with a traditional circumscription of “species,” while denying it any special ontological status or reality, using it only as a heuristic notion that could ground attention as diverse and often inconclusive scientific analyses advanced (Atran, 1998). Likewise, this working characterization and account of “religion” may help to orient research, but it should not be mistaken for a final point of reference and explanation. The chosen conduit metaphor is of an evolutionary landscape that constrains (initially randomly) interacting humans, as they “walk” through life, onto converging life

paths that involve cognitions of supernatural agents who deal with emotionally eruptive existential anxieties and regulate long-term social commitments. Within this framework, an explanatory account, or “theory,” of religion, would build from the “bottom-up” in terms of the cognitive, emotional, and social microprocesses that assemble interacting individuals into religious traditions. In the end, “religion,” like “culture,” may turn out to be more of an analytic hodgepodge of “family resemblances” than a natural kind with systematic properties (on “culture,” see Atran et al., 2005).

CHAPTER 18

Cultural Evolution and the Shaping of Cultural Diversity

LESLEY NEWSON
PETER J. RICHERSON
ROBERT BOYD

This chapter focuses on the way that cultures change and how cultural diversity is created, maintained, and lost. Human culture is the inevitable result of the way our species acquires its behavior. We are extremely social animals, and an overwhelming proportion of our behavior is socially learned. The behavior of other animals is largely a product of innate, evolved determinants of behavior combined with individual learning. They make quite modest use of social learning, whereas we acquire a massive cultural repertoire from the people with whom we associate (Richerson & Boyd, 2005, Chap. 2). Expertise in exploiting our environment, values about what matters in life, and even feelings about whom to trust and whom to hate are mostly “absorbed” from those around us.

What is more, we are very adept at transmitting cultural information to others, not only through frank teaching but also through the constant social interaction characteristic of human life: mutual observation and casual conversation during which behaviors and beliefs are seen, described, evaluated, and generally

gossiped about. As Rogoff, Paradise, Mejia Arauz, Correa-Chavez, and Angelillo (2003) note, teaching in traditional cultures is not like formal schoolwork or the school-like teaching seen in modern societies and families. Children learn by close observation, followed by concrete participation in the activities of everyday life, gaining greater participation as they master more complex skills. Adults teach in the sense that they tolerate children’s participation and lightly guide and structure children’s learning experiences.

Cultural diversity inevitably develops in the course of cultural transmission. Individuals are constantly misremembering and thus varying some piece of culture, as well as making more deliberate variations. Learners often put their own personal twist on what they have been taught. Once such a new “cultural variant” exists, there is a tendency for it to be preserved. A woman’s children may pick up a variant she created and spread it among their friends at school, who might then pass it on to their families. If such cultural processes were all that were operating, cultural diversity would in-

crease without bound. In fact, although cultural diversity is great, it is not boundless. Other social processes operate to select and winnow away less useful cultural variants. This results in members of the same culture and subculture sharing a large proportion of their cultural information.

The sharing of cultural information allows groups of humans to interact and to cooperate effectively, so it is essential that some processes act to limit diversity. If such processes did not exist, human societies could not function as they do. Languages and dialects are the canonical examples of shared cultural information. For members of a social network to be able to communicate, their vocabulary and grammar has to overlap to a large extent. Thus, conformity to common usage acts powerfully to limit linguistic diversity. Variation in language usage does exist at the individual level, but the bulk of the variation is concentrated between communities that historically had little reason or opportunity to communicate with one another. When groups do not interact, their languages evolve separately and in time become mutually unintelligible. Linguistic conformity and diversity are especially important in explaining patterns of cultural change. Much cultural transmission involves language, and much cultural variation thus follows patterns of linguistic variation (Pagel & Mace, 2004). Of course, the spread of cultural variants can defy linguistic barriers, especially in the current “global village”; a great majority of the world’s people know that Coca-Cola is a soft drink and that a Big Mac is a certain American-style meat sandwich. However, as a general rule, cultural diversity between communities must exist because some tools, techniques, and economic practices are suited to the situation of a given community and some are not. As cultures change, they adapt, with less successful cultural variants being forgotten or modified.

Our objective in this chapter is to dissect the process of cultural change, and the divergence and merging of cultures by describing the complex concatenation of forces that shape cultural diversity—forces that, for example, act to wipe out whole languages and technologies, while constantly spawning new dialects and new technologies. We draw a number of qualitative inferences from theory and available data, but the quantitative study of the dynamics of cultural diversity is still in its infancy.

The current pattern of cultural diversity among our species is the result of the changes in the knowledge, practices, and beliefs that have occurred over the last 70,000 years or so. Genetic evidence revealing how closely related all modern humans are suggests that we are descended from a relatively small population with limited individual and subcultural variation (Harpending et al., 1998). Between 50 and 100,000 years ago this population began to grow and spread, first in Africa, then across the world. With this expansion came a diversification of languages, subsistence systems, patterns of social organization, and other cultural features. As more complex societies began to evolve about 5,000 years ago, subcultures—classes, castes, occupational groups, and religious faiths—began to diversify *within* cultures to a degree not seen in earlier tribal scale societies. Meanwhile the growth of complex societies began to sweep away the former diversity *between* small-scale societies. Each of the many elements making up the vast body of information comprising a population’s culture can change in a variety of ways, so the potential for creating new combinations of ways to perceive and interact with the physical world is staggering. On top of that, there are many possible variations on how to define social interaction, interaction with the biological environment, and so on.

We are not aware of any comprehensive attempt to quantify cultural diversity and its change through time, although many partial catalogues exist (e.g., Fearon, 2003). Jorgensen’s (1980) classic study of the ethnographic diversity of Western North American Indians analyzes the patterns of covariation to be found among the different dimension of culture in his dataset. Cultural anthropology textbooks use various simplifying schemes to sketch the spatiotemporal patterns of diversity (Johnson & Earle, 2000). Many studies have been drawn from the Human Relations Area Files, a large database of ethnographic and historical data (Murdock, 1967, www.yale.edu/hraf/).

A number of researchers have attempted to infer the history of related groups of peoples by employing the methods used by biologists to determine the evolutionary descent of species (Cavalli-Sforza, 2000; Moylan, Graham, Borgerhoff Mulder, Nunn, & Håkansson, 2005; Pagel & Mace, 2004). These studies are often based on linguistic data; we probably

know more about language change and diversity than about any other segment of culture (Nettle, 1999), except perhaps technology (Basalla, 1988; Needham, 1987). The Centre for the Evolutionary Analysis of Cultural Behavior, based at University College London, has begun the project of constructing quantitative databases of archaeological data (www.ceacb.ucl.ac.uk/home/), but, as with biodiversity, the many dimensions of cultural diversity defy easy analysis (Dunn, Terill, Reesink, Foley, & Levinson, 2005).

Our approach to describing cultural change is to view it as an evolutionary process. However it is important first to point out that we do not use the word *evolution* in the sense first used by the 19th century founders of anthropology to mean *progress* from less complex to more complex societies (Burrow, 1966). We use it in the sense used by Darwin. Just as people acquire their genes from their parents, they acquire their culture from the people they encounter. They model their behavior on that of significant others in their lives. These cultural “models” may actively communicate values, skills, and information; they may be passive objects of imitation or emulation, or they may play some intermediate “teaching” role (Rogoff et al., 2003). Whichever way transmission occurs, the models from whom an individual acquires his or her culture are limited in number, a small sample drawn from the larger population. In principle, any individual might learn some element of culture from any other individual in the world, but in practice we usually model our behavior on the behavior of a limited number of people from our own culture and subculture. In principle, an individual can invent a completely novel and personal body of knowledge, beliefs, and values, but in practice people make only marginal changes in the culture they inherit from others.

The transmission of culture between individuals is the engine of cultural replication and change but, for the most part, what any single individual member says or does has little impact on the process of change. Culture and cultural change are best viewed as population-level phenomena. Single individuals are largely prisoners of the culture they inherit but the decisions they make, and the outcomes of those decisions, are what drive cultural evolution. Summed over a *population* of individuals and over some span of time, some culturally char-

acteristic behaviors, beliefs, and values become more common in the population, whereas others become less common, and still others disappear altogether. New cultural characteristics arise and either “survive” and spread through the population or fade away.

Thus, the all-important population-level phenomena of cultural evolution that we describe here emerge from the aggregation of myriad events and decisions at the individual level. A long tradition of social, cognitive, and developmental-psychological research provides us with a basic understanding of cultural transmission, of how information is learned and processed, and how cultural norms are adopted and developed by individuals and groups (e.g., Asch, 1951; Bandura, 1986; Bloom, 2000; Festinger, Schachter, & Back, 1950; Newcomb, 1943; Newcomb, Koenig, Flacks, & Warwick, 1967; Rogers, 1995; Sherif & Murphy, 1936; Tomasello, 1999). Cultural psychologists, by investigating the degree of diversity between and within populations, observe the effects of cultural variation on behavior.

A massive gulf exists between the individual-level social interactions during which cultural variants are acquired and modified and the long-term population-level changes that cause two groups of people to become “culturally different.” However this gulf can be bridged by methods developed by population geneticists to study genetic evolution. Viewed at the population level, “Culture” (i.e., the pool of cultural information associated with a population) has a certain formal similarity to the pool of genes associated with a species. Theorists have therefore capitalized on this similarity to create mathematical models of the cultural evolutionary process (e.g., Boyd & Richerson, 1985; Cavalli-Sforza & Feldman, 1981). Evolutionary biology also furnishes inspiration for empirical investigations of cultural evolution (Baum, Richerson, Efferson, & Paciotti, 2004; Insko et al., 1983; Jacobs & Campbell, 1961; McElreath et al., 2005).

In other words, applying these methods provides the opportunity to investigate cultural change in much the same way that changes in the composition of a population’s gene pool can be investigated. Studying culture in this way is not “biological reductionist” in the sense that it relies on an assumption that individuals are biologically determined to acquire specific behaviors (Richerson & Boyd, 2005).

What it does rely on is the assumption that humans are genetically adapted to acquire some of the cultural characteristics of the people with whom they associate. Few would disagree with this. Undoubtedly genes play some role in the directions in which cultures evolve, but this role is limited. For example, the human senses of taste and smell undoubtedly place constraints on the evolution of diets, but this is far from deterministic. Many cultures have evolved cuisines rich in spices and aromas that generate alarm and disgust in the “untutored” palate. In the very long run, cultures actually create the environments to which its members must adapt genetically. This leads to the co-evolution of genes with culture.

The main purpose of theoretical models of cultural evolution is to investigate the large-scale and long-term consequences of the aggregate of individual-level events. However, cultural evolutionary analysis can also be performed in reverse; given a characteristic, such as the human propensity to cooperate in large groups of distantly related people, models can help to investigate what sorts of individual-level properties might give rise to such an outcome. Only in the simplest cases is this exercise trivial. By using mathematical models to create predictions about cultural evolution that can then be tested, cultural psychology will more fully develop its potential as an experimental science.

Evolutionary analysis of culture provides an answer to the commonest criticism leveled at cultural explanations of human behavior—that they are not actually explanatory. The suggestion that people behave according to the dictates of their cultures is little more than description, and many social scientists are more impressed by the power of explanatory systems, such as economics and behavioral ecology, which allow deep causal analyses of human behavior. The fact that cultural variation exists is important in its own right, but these social scientists also want to explain how the variations arise. Cultural evolution undertakes to provide this explanation. The basic format of evolutionary analyses is a virtuous circle. Individuals in one sense are prisoners of their cultures. What we believe, how we behave, and so on, are largely based on what we acquire from our culture. But, at the same time, our decisions about which elements of the culture we encounter to adopt and the effects of those de-

isions upon our lives are the most important motors of cultural diversification. In the long run, culture is shaped by the actions its individual members and the consequences of those actions.

Evolutionary theory and empirical studies allow us to describe the behaviors and processes that maintain and destroy cultural variation. We review this work with an emphasis on contemporary cultural change. Losses of cultural diversity due to the apparent assimilation of smaller cultures and the “globalization” of some aspects of culture are often noted. On the other hand, new variations arise and many old variants stubbornly resist conversion to modernity. Commentators commonly express the fear that cultural change in the modern world will inevitably lead to homogeneity as the members of smaller cultures are assimilated into larger ones. We argue that the processes of cultural evolution will ensure that cultural diversity is maintained. The pattern of cultural diversity has changed and is likely to change further, however, so it is likely that culturally different groups will become less distinct.

THE CAPACITY FOR CUMULATIVE CULTURE

For the last 30 years or so, most of the scholars who have applied Darwinian thinking to human behavior have investigated the evolution of psychological mechanisms acquired via the genetic rather than the cultural inheritance system. Insights developed in the 1960s and 1970s into how natural selection acts on behavioral genes (Hamilton, 1964; Trivers, 1971, 1972; Williams, 1966) have led to a revolution in our understanding of the reproductive and social behavior of nonhuman animals and have formed the theoretical basis of many investigations of human behavior. The idea that evolved psychological mechanisms interact with environmental circumstances to produce specific behaviors inspired many testable hypotheses, and much fruitful science has been accomplished (e.g., Buss, 1999; Cronk, Chagnon, & Irons, 2000), but inevitably the extent to which such studies can explain human behavior is limited.

We humans undoubtedly possess many genetically evolved psychological mechanisms that allow us to make sense of the environment, and that structure the ways we perceive

information from our senses. We share many of these cognitive capacities with other animals. But among the evolved mechanisms unique to humans, the most important the ones govern the way we acquire, use, modify, abandon and pass on cultural information. Behavioral characteristics acquired through our genetic inheritance cannot begin to explain the complexity and diversity of human behavior. Humans thrive in a wide variety of natural habitats, consuming a wide variety of diets and constructing a complicated variety of social systems. Yet among the 6 or so billion humans worldwide there is far less *genetic* diversity than among the fewer than 200,000 chimpanzees occupying African forests (H. Kaessmann & Pääbo, 2002; H. Kaessmann, Wiebe, & Pääbo, 1999; Tamura & Nei, 1993).

The classical explanation for greater diversity of human behavior is that individual humans *learn* behavior from one another rather than rely on instinct. This is also too simplistic. Animal species as diverse as rats, pigeons, and fish, as well as chimpanzees, have been found to acquire behaviors through social learning (Moore, 1996). Once a behavior exists in a population, the likelihood increases that the behavior will be exhibited by members of subsequent generations. This can result in persistent differences between the behaviors observed in separate groups of animals. Such behavioral diversity, which cannot be explained by genetic or environmental differences, is by many definitions evidence of culture (Byrne et al., 2004). Comparisons of the behaviors observed in the six most widely studied chimpanzee populations revealed that each community possesses a distinctive repertoire of behaviors that, if observed in human populations, would be reported as cultural differences (Whiten et al., 1999). However, the chimpanzee cultural repertoire is very limited compared to the powerful technologies and complex institutions that characterize human cultures.

Human cultures are more complex because they are the product of many generations of *accumulated* cultural change. The cultures of other animals—even of chimpanzees—show at most very modest signs of cumulative improvement (Boyd & Richerson, 1996). Useful behaviors may be acquired through social learning, but these are all behaviors that the individuals could, and often do, learn on their own. In human cultures, by contrast, each newborn member has access to a vast body of knowledge and

know-how that is far greater than a single individual could learn by experience, even in several lifetimes of experience. Learning and invention enables individuals to contribute to the body of cultural knowledge, but no one starts from scratch. Just as *genetic* evolution is the accumulation of small changes in *genes* that gave an advantage to the organisms that carried them, *cultural* evolution is a process that allows useful *cultural* variants to be acquired, improved upon, then passed on. Small success builds on small success.

Experimental studies comparing human and chimpanzee abilities to acquire behaviors by social transmission show that we are the more adept imitators by a large margin (Tomasello, 1996; Whiten & Custance, 1996). The behavior of apes who have observed a demonstration suggests that they rarely copy a precise procedure but are inclined to use it as a guide to developing their own solution to a problem (Whiten & Custance, 1996). Children, on the other hand, are such faithful imitators that they have been found to persist in using a demonstrated technique for obtaining a reward that apes soon abandon for a more efficient method of their own devising. Many years of observing chimpanzees in the wild has yielded little evidence of what might be construed as one chimpanzee trying to tell another something useful (Byrne, 1995); however, for a more generous interpretation of chimpanzee social learning, see Boesch (2003). High-fidelity imitation and evaluative communication or teaching (Castro & Toro, 2004) seem to be a derived package of cognitive and motivational traits that provide the psychological foundation for our complex cultural repertoires.

Cultural diversity in humans grows directly out of the cumulative evolution of complex cultural repertoires. Part of this diversity is due to historical happenstance. Cultures evolve in partial isolation and tend to diverge from one another as small differences accumulate generation by generation. The purest examples are from the symbolic part of cultural repertoires, such as language (Bettinger, Boyd, & Richerson, 1996; Labov, 2001; Logan & Schmittou, 1998; Nettle, 1999; Thomason, 2001), whereas variants such as technical skills are influenced by environmental factors. When populations live in different habitats, adaptive processes of cultural change lead to diversification, because variants appropriate to the respective habitats are most likely to be adopted.

Adaptive cultural change can, of course, also lead to convergence when populations live in similar environments (Johnson & Earle, 2000). Groups that make their living in a desert will likely develop some similar practices whether the desert is in Australia or Tunisia. However, adaptive processes also leave ample room for historical factors that maintains variation between populations, even if their survival problems are similar. Complex cultural adaptations can vary along many dimensions. The “design topography” is probably quite rough and likely to lead to many local optima. For example, the problem of carrying and storing water can be solved in a number of ways, and a culture that has already developed the skill of weaving waterproof baskets may never acquire the technology for producing pottery and vice versa. Partially isolated cultures evolve along different trajectories even if the only processes operating are adaptive and deterministic (Boyd & Richerson, 1992a).

An ability and desire to influence and to be influenced are important elements of the psychological processes that govern the transmission of cultural information, but again, there are more complexities. If the transmission of cultural information were simply a matter of demonstration by those who are knowledgeable and faithful copying by those who are naive, cultural evolution would be slow and very similar to biological evolution. Copying errors would be the only source of variation and variants would be selected by natural selection alone. Cultural evolution is rapid and allows rapid adaptation, because the human capacity for culture includes psychological mechanisms that enable individuals to introduce variation and make better than random choices between the cultural variants to which they are exposed (Durham, 1991; Richerson & Boyd, 2005). Classic social-psychological investigations of social influence and persuasion have show that there is a fair amount of consistency in the social conditions that result in individuals and groups remembering some things and forgetting others, or adopting some norms and attitudes and eschewing others (Asch, 1951; Hovland, Janis, & Kelley, 1953; Sherif & Murphy, 1936). As we argue later, it is likely that the “decisions” this involves also rely on evolved psychological mechanisms that increase the likelihood of individuals ending up with the optimum arrangement of beliefs and behaviors that their culture has to offer.

BIOLOGICAL AND CULTURAL EVOLUTION

The molecular mechanics of the biological inheritance system are now well understood and the idea that a physical substance (DNA) carries inherited information has become part of mass culture. Richard Dawkins (1976) proposed a Darwinian analysis of cultural change in which “memes” are analogous to genes. Dawkins envisaged memes to be discrete replicators that spread through a population and which can be worked on by natural selection. One problem with this way of thinking about cultural evolution is the variableness of cultural variants. Some are discrete units of information (e.g., the fact that chili peppers are safe to eat despite their sensory effects), but others (e.g., beliefs about what constitutes appropriate work for a lady) are more complex and perhaps cannot be faithfully transferred from mind to mind (Sperber, 1996, Chap. 5).

We cannot, at least not yet, define the nature of a “meme” or even know whether it is useful to think of culture as a collection of units, but this lack of understanding does not prevent a Darwinian analysis of cultural change. Many schemes for transmitting heritable variation are susceptible to a broadly Darwinian analysis (Richerson & Boyd, 2005, pp. 80–94). Remember that Darwin laid the foundations of evolutionary analysis with no knowledge of genes, what they do, or how they mutate. For the evolution of an information system to be analyzed, only two criteria need be met: (1) The system must contain characteristics that can be passed on (i.e., inherited), and (2) these characteristics must vary between individuals in a population. Darwin recognized that variants continue in a population as long as they continue to be inherited, and that the probability of their recurrence in the next generation can be affected by a number of forces. Exactly the same can be said about the information, technology, beliefs, ideas, preferences, habits, expertise, and all the other potentially variable elements that make up culture. The key to evolutionary analysis is identifying and investigating the forces that affect the continuity of cultural characteristics and the emergence of new ones.

The variability of cultural elements is undoubtedly shaped to some extent by preferences laid down by human genetic inheritance (Barkow, Cosmides, & Tooby, 1992; Daly & Wilson, 1983; Durham, 1991), but when it co-

mes to deciding how to behave, culture routinely overwhelms biology. For example, military training (Richerson & Boyd, 1999) and religious indoctrination (Wilson, 2002) often lead people to perform feats of altruism on behalf of their community, fellow believers, or a whole nation, without in anyway benefiting their “selfish genes.” More prosaically, individuals are routinely persuaded to endure pain to behave according culture’s norms. For example, many Western women feel compelled to dance while wearing 3-inch stiletto heels. Given the permanent problems with the feet and back that this has been observed to cause (Rudicel, 1994), the wearing of currently fashionable female footwear bears a disturbing similarity to the foot-binding practices in 19th-century China (Brown, 2004). The need to avoid causing more immediate or severe damage does seem to set limits on cultural evolution, however. Actual amputation of healthy feet and a preference for hand walking are unlikely to become cultural norms.

The constraints that the human genetic endowment places on cultural evolution have to be seen in the context of the effect that culture has had on the composition of that endowment. The practices and preferences that a population acquires through cultural evolution also affect the selection of genes, such as when a cultural preference for certain physical characteristics makes it more likely that an individual with these traits is chosen as a sexual partner, or less likely that she is chosen as a victim of infanticide.

Gene selection can also occur as a result of two less direct mechanisms. First, the adoption of a cultural practice can result in some individuals thriving at the expense of others. For example, populations that learned how to extract a nutritious food source (milk) from domesticated grazing animals were better equipped to exploit the grassland habitat, but not all members of the population would have benefited equally. Those lucky enough to have a genetic makeup that enabled them to continue drinking milk beyond the age of weaning were better able to tolerate the new food. After a number of generations, the migration or poor survival of individuals who could not produce the enzyme that breaks down the milk sugar (lactose) would have made the genotype that confers lactose tolerance virtually universal in populations for which milk is an important component of the diet (Simoons, 1969, 1970). Sec-

ond, the practices of a population may alter the environment in such a way that the selective pressures on the population are changed. An example of this is the increase in the incidence of the sickle-cell genes in West African populations that began to cultivate yams (Durham, 1991). The growing of yams required the cutting of clearings in the rain forest. This increased the amount of standing water, which in turn increased the prevalence of malaria-carrying mosquitoes. And this, in turn, increased the relative chances of survival of individuals who were protected from malaria because they carried a sickle-cell gene.

The preferences and practices inherited culturally can also shield transmitted characteristics from the action of natural selection (Laland, Richerson, & Boyd, 1996). For example, if the range of a species of animal widens to include regions with colder climates, those individuals whose physiology and anatomy make them better able to withstand the cold have a selective advantage. In the case of humans, individuals with a round, high surface-to-volume ratio body shape require less energy to remain warm than do individuals who are tall and thin. However, clothing, fire, and other culturally evolved methods of protecting against the cold reduce the selective pressure exerted by nature and allow a population to maintain a wider variety of body shapes or to evolve toward body shape that meets a *culturally* evolved preference rather than one that is environmentally expedient. Culture enables groups of humans to create (and constantly recreate) the ecological niche they inhabit (Odling-Smee, Laland, & Feldman, 2003). Inevitably, as in all ecological niches, the composition of the gene pool changes as some individuals achieve greater reproductive success. These genetic changes can then influence the course of cultural evolution.

The coevolution of genes and culture creates opportunities for behaviors to evolve that could not have evolved through the action of natural selection on genes alone. Modern human behavior is the product of many hundreds of generations of interplay between the genetic and cultural inheritance systems. In chimpanzee groups, powerful, successful alpha males usually mate with all the females in their group, as they become fertile, and are aggressive to rival males. Stronger males therefore have more offspring than weaker ones, and their male offspring are likely to inherit not only the father’s strength but also genes that promote taking ad-

vantage of strength. The evolution of a group of primates with the capacity for culture (e.g., our early hominid ancestors) can go in a quite different direction. The females of such a group might *culturally* evolve a preference for males who are not promiscuous, who help provision their offspring, and who are reluctant to fight. In this *cultural* environment, females may still prefer large strong capable males, but they especially favor those with genes that endow them with a tendency to suppress sexual and competitive aggression to devote effort to productive activities.

Biological evolution can explain altruism between kin and individuals who develop a long history of reciprocal mutual aid, but the extensive cooperation seen in humans between nonrelatives is a puzzle from the point of view of standard evolutionary theory. Gene-culture coevolution provides an explanation for the evolution of behaviors that allow humans to create cooperative social groupings of nonrelatives (Richerson, Boyd, & Henrich, 2003), but it is not the only explanation entertained by evolutionists (Henrich et al., 2003). Groups that interact infrequently can evolve very different cultural traditions and institutions. The ones with cultures that enable or encourage their members to behave more effectively will thrive at the expense of groups that are less culturally well endowed. Therefore, cultural evolution is more susceptible to group selection than is genetic variation. Groups that developed traditions of punishing selfish behavior that was detrimental to the group as a whole may well have been more successful than groups that tolerated more individualistic behavior. Genes that facilitate cooperation could have arisen in such groups, because the cultural environment would have favored individuals who were more docile and willing to behave in accordance with cultural norms. Repeated coevolutionary cycles eventually could drastically modify the psychological mechanisms that influence human social interaction (Boyd & Richerson, 1992b; Boyd, Gintis, Bowles, & Richerson, 2003).

Note that sharing knowledge with others is potentially a form of altruism and also a potential means of exploiting others by propagating self-serving ideas (Cohen & Vandello, 2001). Language vastly expanded our capacity to transmit both useful and deceptive information to others (Knight, Studdert-Kennedy, & Hurford, 2000). Complex culture can arise only if mem-

bers of a group socialize their youngsters to be informed and “properly behaved” fellow members of their cultural group, and it can only be maintained if a large enough group of individuals continues to hold, share, and pass on the information possessed by the group. The number of people needed to support cultures of hunter-gatherers is surprisingly large, as Henrich (2004) shows in his comparison of the technological complexity of a number of hunter-gatherer cultures. When Europeans first encountered the aborigines inhabiting Tasmania, their population of 4,000 had a very limited tool kit compared to that of mainland aborigines. Archeological investigation has revealed that during the 10,000 to 12,000 years since rising sea levels caused Tasmania to be cut off from the mainland, the isolated islanders gradually lost many skills their ancestors had possessed, including fishing and the making of clothes.

The diversity of languages and other symbolic elements of culture is interesting in this light because divergence of language essentially socially isolates groups. Why did a characteristic evolve that places constraints on the complexity of culture? In small-scale societies, the people who are subject to the same norms of cooperation also speak the same language or dialect. Did rapid change in language become established because the resulting dialect variation serves to protect the members of a cultural group from members of groups with which they no longer regularly communicate? When groups can no longer effectively communicate, members are less likely to inadvertently betray their own group’s cultural secrets to competing groups, and they are also unlikely to be manipulated by malign advice or comments from competitors. In modern contexts, linguistic variation grows rapidly along social fault lines, generating new linguistic diversity, and perhaps protecting and generating other forms of cultural diversity (Labov, 2001). Contrariwise, the establishment of standard forms of speech via education and mass media is arguably responsible for the emergence of national sentiments and the destruction of much small-scale cultural variation in the large societies of the modern period (Anderson, 1991). Most likely, the social psychology that we deploy in deciding whom to trust for purposes of imitation and teaching has innate elements that were built by gene-culture coevolution.

That humans are highly cooperative animals is supported both by common experience and

experimental evidence. People may complain about the selfishness and dishonesty they encounter, but the fact that such behavior is considered worthy of complaint is telling. Our societies only function because there is a general level of trust, an expectation that we will be trusted, and a willingness to identify and punish individuals who behave in an untrustworthy way. To investigate the nature of human cooperativeness, economists have developed games for people to play in the laboratory that give subjects the opportunity to behave selfishly or cooperatively in an environment where social cues that encourage cooperation can be controlled.

One of these games, Ultimatum, is played between two players who are never known to each other. One player is randomly selected to be the “proposer,” with the task of proposing how a sum of money will be divided. The other, the “responder,” can accept this division or reject it. If the proposal is rejected, neither player gets any money. This game played between selfish rationalists would result in the proposer getting the maximum share possible and the responder accepting whatever remains; even a 99 to 1 split would be accepted by a selfish rationalist, because anything is better than nothing. The overwhelming conclusion of these studies when carried out in Western populations is that humans do not behave like selfish rationalists. Most proposers share the money 50–50, and many responders reject offers smaller than 25–30% of the proposer’s windfall.

In a series of studies that exemplify current quantitative cross-cultural research, Henrich et al. (2004) took the Ultimatum game to 15 cultures with varying degrees of integration into the global economic system. They found that the more contact and integration the groups had with modern market economies, the more likely their members were to choose a 50–50 distribution. The more isolated the culture, the more likely their members were to propose and accept offers that those in market economies would find unfair or bizarre. The family-based Machiguengan culture of southeastern Peru both propose and accept very low offers, and members of the Gnaou and Au culture of Papua New Guinea make offers of a larger than 50% share. (The larger offers were likely to be refused because, in this culture, accepting such offers would make the responder uncomfortably indebted to the proposer.) The 50–50 split commonly agreed upon by members of market

economies perhaps reflects a greater exposure to the cultural tradition of fair dealing with strangers that allows modern markets to operate. Even if a concept of how to deal with strangers is partly a cultural construct, however, in none of the cultures did players behave like selfish rationalists—hence, the conclusion that humans possess a genetically evolved tendency to behave cooperatively. The innate tendencies are reinforced, however, by culturally evolved practices that promote cooperation and trust.

Human social instincts also include what may be thought of as cultural tools, such as the capacity to acquire rapidly a sophisticated symbolic system of exchanging information (language), a tendency to categorize human groups on the basis of appearance or dialect, or symbolic markers such as dress (Gil-White, 2001; Richerson & Boyd, 2001), and a set of preferences or biases that influence which cultural variants an individual chooses to acquire (Richerson & Boyd, 2005). These preferences serve as a quick means of choosing which cultural variants to acquire. Such shortcuts are necessary because, as cultures accumulate values, skills, knowledge, and so forth, their members have an increasingly wide choice of variants to adopt. This makes it increasingly difficult, and eventually impossible, for members to even be aware of every cultural variant available. If humans had spent a large proportion of their time investigating the value of each variant, culture would have ceased to be effective as a way of enabling individuals to gain expertise rapidly. Individuals who made reasonably good decisions quickly would have been more successful than those who made bad decisions and *also more successful* those who made good decisions but only after much deliberation (Gigerenzer & Goldstein, 1996). The ability to make sensible judgments quickly would have been reflected in the number of children an individual produced, so natural selection would have favored individuals with innate preferences that made such behavior most likely.

One obvious rule of thumb to follow when deciding whether to replace a cultural variant would be to avoid replacing a familiar belief or behavior with a new one, unless there is a good reason to do so. There are also often practical reasons for maintaining the status quo. Standardizing driving practices worldwide, so that everyone drives on the left-hand side of the

road, may bring long-term benefits, but the short-term expense and chaos it would bring has caused few countries to even contemplate it. In many domains, however, humans readily investigate novel cultural variants. Judging by the alacrity with which people embrace unfamiliar foods, be it “ethnic cuisine” or Western “fast food,” we are relatively unconservative in our taste in food. Historical inertia is profoundly important in characterizing a culture, but individuals who fear novelty and doggedly follow old ways would have been at a disadvantage compared to those willing to consider promising innovations.

One reason for suspecting that a new cultural variant is worthwhile is that other people have adopted it. The social provenance of a variant is usually easier to establish than its actual worth, and it is reasonable to assume that at least some of the individuals who adopted the variant would have taken the trouble to evaluate its worth. A good rule of thumb to follow when contemplating what cultural variants to adopt is to imitate behaviors that are popular with people similar to oneself, who seem confident in what they are doing or are considered worthy of admiration (Boyd & Richerson, 1985; Henrich & Gil-White, 2001). Research generally supports the existence of such preferences in people’s conformity to social norms (Asch, 1956; Sherif & Murphy, 1936) and adoption of attitudes (Chaiken, 1979; Simons, Berkowitz, & Moyer, 1970; Wright, 1966).

The transmission of cultural information depends on which cultural variants individuals acquire, so, at the population level, these preferences can be seen as “forces” that influence the direction of cultural evolution. The magnitude and interaction of a number of forces affect the ways that cultures change.

THE PROCESSES OF CULTURAL EVOLUTION

Any particular bit of cultural variation is likely to be subject to a complex of processes, with some tending to increase its future representation in the culture, and others, decrease it. It is impossible to predict precisely how a culture is likely to change because of the complex concatenation of forces that influences this change. This does not mean, however, that cultural change is unfathomable; it is complex but not random. The evolutionary analysis of cultural evolution follows the same pattern as genetic

evolution, although the details are considerably different.

First of all, consider the inheritance system. In the *genetic* inheritance system, the information, coded in genes, is transmitted from parents to offspring with considerable fidelity. The transmission process itself merely recreates the population from generation to generation, with no change in the frequencies of genes. The cultural inheritance system is not nearly so rigid. Transmission of cultural information can be from parents to offspring, from other adults to children, or among people of similar age and experience. Cavalli-Sforza and Feldman (1981), following the terminology used by epidemiologists, termed the three prototypical types of transmission as follows: *vertical*, *oblique*, and *horizontal*, respectively. To the extent that such patterns of transmission operate by faithful teaching or imitation, the looser structure of cultural transmission still acts to replicate the status quo. As in the genetic inheritance system, the transmission process itself does not affect the frequency of cultural variants. Whether a transmitted vertically, horizontally, or obliquely, cultural variant is still passed on.

Evolution occurs in both the genetic and cultural inheritance system because of forces that cause the frequency of variants in the population to change. Some of the forces are the same in both systems, so it is worthwhile to look for a moment at the simpler genetic evolutionary process.

The extent to which a *gene* is present in the next generation depends on four forces:

1. *Natural selection*—The genes of individuals who are more efficient converters of environmental resources to offspring are more highly represented in the offspring generation.
2. *Mutation*—Copying errors and damage to genes cause random changes to individual genes, slightly reducing the level of parental genes and generally increasing genetic diversity.
3. *Drift*—All populations are finite, so there is never a perfectly probabilistic distribution of parental genes for reasons that have nothing to do with their effects on the organisms that possess them.
4. *Migration*—Flows of genes between subpopulations who might be adapted to slightly different environmental conditions

reduce the effect of natural selection and drift.

The basic task for cultural evolutionists is the same as that of evolutionary biologists: to identify and investigate the forces that affect the transmission of characteristics in a population (in this case, the *cultural* characteristics) using mathematical models and empirical investigation. The purpose of the models is not to produce precise descriptions or predictions of cultural change, but to investigate the operation of forces at the population level. They are useful in the same way that meteorological models are useful for forecasting (but not precisely predicting) future weather. The systems that affect weather are so complex that even vastly complex models cannot predict the detail of weather and climate change. However, relatively simple models provide useful broad-brush explanations and forecasts that improve as our understanding of meteorological processes increases.

First of all, changes in the frequency of cultural variants that occur over time are influenced by the same four forces identified as influencing the remodeling of the combination of genetic variants that exist in a population:

1. *Natural selection*—The prevalence of variants decline if they are possessed by people who have fewer offspring.
2. *Mutation*—Random changes in cultural variants occur when learners do not reproduce them accurately.
3. *Drift*—The flow and transmission of cultural information cannot be completely uniform throughout a population, so inevitably there are random differences in the cultural variants to which groups are exposed. Groups within a culture whose members have little contact with one another increasingly diverge.
4. *Migration*—New variants to a population via migration result in decreased prevalence of the old ones.

The evolution of culture differs from the evolution of genes most strikingly in being subject to what we call “decision-making forces.” Because cultural transmission is spread out over a significant fraction of our lives, the cultural variants we adopt are influenced by the behavioral choices of the individuals taking part in our social interactions. Our choices

(consciously or unconsciously) about what we say or display to the people with whom we interact affect which of our behaviors and beliefs they are exposed to. Once a cultural variant has been displayed, its transmission then depends on the choice made (consciously or unconsciously) by each observer. Will he adopt it, ignore it, dismiss it, reject it, not notice it, or forget it? Evolved cultural acquisition tools create innate preferences or “biases” that incline a person to adopt some variants rather than others. These biases, operating in each individual member of a culture, sort among existing cultural variants, causing some to increase in frequency and others to decrease. Donald Campbell (1965) called biases “vicarious selectors,” because he imagined that the biases themselves ultimately arise from the action of natural selection on the genetic and cultural features of the biases. Vicarious selectors evolve because being naturally selected is a costly business, and behavioral mechanisms to anticipate and forestall it are favored. However, the higher order effects vary depending on the type of bias.

Innate cultural acquisition tools are undoubtedly shaped and sharpened by learning, both individual and social learning. For example, once a child reaches adolescence, she may begin to imitate her parents less and abandon some vertically acquired cultural variants in favor of those of her peers or teachers. This change may occur because her culture expects adolescents to begin to ignore parental influence, but the adolescent may also have had personal experiences that lead her to realize that her parents’ judgments are often not reliable in some areas. And there might also be an innate component to teenage rebellion. In ancestral populations, children who began to question parental authority once they approached sexual maturity may have had greater reproductive success than those who maintained childish compliance. Any genes that encouraged “teenage rebellious” behavior would then have been genetically selected.

Establishing the factors that influence the adoption and development of social norms by individuals and by groups has been the aim of much very fruitful research in social psychology. Although most social psychologists have not approached the study from an evolutionary perspective, their findings are consistent with the operation of psychological mechanisms that evolved, because they encouraged quick and reasonably effective decisions on which

cultural variants to acquire (Gigerenzer & Goldstein, 1996). For example, the “elaboration likelihood model” of Petty and Cacioppo (1986) describes two routes by which exposure to a message leads (or fails to lead) to a change in attitude. In taking what they call the “central route to attitude change,” an individual decides to take up a new cultural variant by considering the content of a persuasive message. However, the “peripheral route to attitude change” provides an alternative decision-making mechanism for those who are unable or lack the motivation to elaborate on the content of the message. Instead, a quick assessment of peripheral cues (e.g., pleasant images or emotions, or indicators of expertise) associated with the source of the message and its delivery provides the basis of evaluation. Attitudes formed by the peripheral route are, however, less stable and less likely to predict behavior than those formed by the central route.

Boyd and Richerson (1985) considered three “learning biases” that arise from the way individuals decide which cultural variants to adopt.

1. *Content-based bias*—Individuals choose to adopt a cultural variant based on consideration of the variant itself. Essentially they take the “central route” (Petty & Cacioppo, 1986) to choosing a cultural variant. Some variants are clearly useful or superior to the alternatives. When the best choice is not so obvious, learners can weigh costs and benefits or determine how consistently a new variant compares with those that have already been adopted.

2. *Model-based bias*—Individuals can choose to adopt cultural variants based on consideration of the social provenance of the variant. In many cases, it may be more expedient for a learner to avoid the trouble of weighing whether a cultural variant is worth adopting and simply look at others who have adopted it and determine whether they are worthy of imitation. Are they happy, confident, and successful in terms with which the learner identifies? The literature on persuasion provides ample evidence that such considerations are very influential in individuals’ decisions (e.g., Perloff, 2003). Prestige systems are usually based on symbols with which members of a culture identify. People in a given culture or subculture share a common definition of “prestige” and the behavior that defines it. For example, some English speakers (consciously or unconsciously) attach more significance to informa-

tion delivered with a “posh” accent, whereas others may favor other accents.

3. *Frequency-based bias*—Individuals can choose to adopt a cultural variant based on considering how popular it is. Very common variants are likely to have been adopted and kept for good reason (Henrich & Boyd, 1998). Individuals with a tendency to copy the most popular behavior are therefore likely to benefit from the experience of their fellow group members. In many cases, conforming also prevents a naive individual from inadvertently breaking some implicit rule of cooperation and risking punishment by fellow group members. Even if the practical benefits of a variant may be limited, there are social benefits associated with sharing the attitudes of other members of one’s social network. If all of your friends have taken the trouble to learn the goal-scoring record of every member of the Premier League, it is a good idea to do the same, or risk having nothing to talk about in the pub on Friday nights. The classic social-psychological experiments of Asch, Sherif, and others established the tendency of humans to adjust their behavior to that of the people around them, and demonstrated the persistence of behaviors and beliefs thus acquired (Asch, 1956; Festinger et al., 1950; Newcomb, 1943; Newcomb et al., 1967; Sherif & Murphy, 1936). More recent research has attempted to characterize the group processes that contribute to the formation and change of social norms (Moreland, Levine, & McMinn, 2001; Postmes, Haslam, & Swaab, 2005).

A learner can only adopt cultural variants that are actually on display, so cultural transmission is also subject to “communicator biases.” Individuals can choose when and to whom they display or communicate the variants in their cultural repertoire.

1. *Situation-based bias*—A tendency to conform to group norms limits the behaviors a person displays based on whether he or she is observed and the social situation. This reinforces the conformist bias on the part of the observers. Research in stereotyping has shown that cultural traditions influence how members of a culture behave in front of members of not only other cultures but also specific groups within their own culture based on sex, age, and occupation (Allport, 1954).

2. *Observer-based bias*—There is evidence

that evolved mechanisms influence contributions to a conversation. When asked what reproductive advice would be appropriate in a range of situations, mothers were more inclined to encourage behavior consistent with reproductive success if they were primed to think in terms of giving advice to a daughter rather than to a friend (Newson, 2003; Newson, Postmes, Lea, & Webley, 2005). In-nate tendencies may also influence how an individual behaves in front of a group versus an individual, or with close friends versus strangers.

Human beings, acting as individuals or in groups, actively attempt to direct or influence cultural change. This introduces two more forces.

1. *Innovation*—Individuals occasionally invent a new cultural variant or (more often) modify an existing one rather than faithfully copying one of the existing cultural variants. The deliberate engineering of more appropriate genes has only begun to be a factor in biological evolution, but adjusting and improving cultural variants is an important force in cultural evolution. Individuals can mix social and individual learning in a way that is reminiscent of Lamarck's (and Darwin's) ideas about organic inheritance (Boyd & Richerson, 1989). Innovation usually takes more effort and is more risky than adopting cultural variants used by others, so it is more likely to occur when existing variants are inefficient. Perhaps existing variants are difficult to understand or to imitate correctly. Changes in the physical or cultural environment may have made them less appropriate. It is in the interest of societies to encourage innovation, because new variants that are more effective can then be copied by others, and the whole society potentially benefits. Populations are likely to be more successful if they evolve institutions that reward successful scholars and inventors and nurture those that show promise. A society that rewards its merely technically competent physicians more richly and more consistently than creative, talented biomedical and social researchers is likely to evolve an increasingly costly, cumbersome, and inefficient health system.

2. *Group decision making*—Conformity and group processes create the tendency for individuals within a network to agree on the cultural variants to adopt, but when the interests

of group members diverge, culturally evolved institutions for collective decision making may be employed (Boehm, 1996). Procedures involved in these more formal decision-making methods also influence cultural change. For example, decisions made through a referendum process are likely to differ from those made by committees of appointed experts. The extent to which a population employs formal decision-making processes is therefore also likely to affect the way a culture changes.

In summary then, cultural evolution is influenced by the same five factors that influence biological evolution:

1. Vertical transmission of variants (from parent to child)
2. Natural selection
3. Mutation
4. Drift
5. Migration

Added to this is the effect of the pattern of cultural variant transmission, which is more complex than the transmission of genetic information. As well as being transmitted from parent to child, cultural variants can be transmitted:

1. Between peers (horizontal transmission).
2. From older/more experienced nonparents to younger/less experienced individuals (oblique transmission).

Because of the greater complexity of cultural transmission, additional forces influence changes in frequency of cultural variants in a population:

1. Bias on the part of the person acquiring the cultural information (learning biases):
 - Content-based bias (based on an evaluation of the variant itself).
 - Model-based bias (based on an evaluation of the prestige or success of the source of the variant).
 - Frequency-based bias (based on an evaluation of the popularity of the variant).
2. Bias on the part of the person displaying or communicating the cultural information (communicator biases):
 - Situation-based bias (based on the communication's evaluation of the social situation).
 - Observer-based bias (based on the com-

municator's evaluation of the observers present).

3. Explicit attempts by members of a culture to influence cultural change:
 - Innovation—the invention of a new cultural variant that may potentially replace older ones.
 - Group decision-making processes—their nature and extent.

This concatenation of forces averaged over a population drives the cultural change the population experiences. By analyzing cultural change in terms of these forces, it is possible to explain patterns of historical cultural change broadly and to make testable predictions about changes in characteristics of cultures, such as patterns of diversity.

THE DYNAMICS OF CULTURAL DIVERSITY

Just as some genes are not passed on and disappear during the course of biological evolution, some cultural variants are ignored and eventually forgotten as culture evolves. However, new cultural variants are also constantly being created. Among the cultural evolutionary forces mentioned earlier, some act to generate cultural variants, whereas others cause variants to become extinct by the selection of some at the expense of others. There are also forces that have no effect on the total number of variants but do influence the way they are distributed. If “cultural diversity” is defined as the number of cultural variants available to members of a population, we can analyze changes in diversity by looking at the balance between the forces that generate new cultural variants and those that select between them. If “cultural diversity” is defined as the extent of cultural difference between groups or regions, we analyze it by looking at the balance between forces that disperse variants and those that create barriers to their dispersal.

Looking at the processes of cultural evolution one by one:

1. *Natural selection*—Any force that selects between variants reduces diversity. Selection normally acts to constrain variation within a culture. Many variants are passed from parents to offspring, so those that are associated with individuals who fail to thrive and produce offspring have a tendency to become less common

in a population. An extreme example is the values and beliefs of cults that requires their members to practice mass suicide or strict celibacy. Cultural variants associated with such groups are less likely to be passed on to future generations. An exception occurs when frequency-dependent selection favors rare types. As labor becomes increasingly divided in a society, for example, natural selection disfavors skills that are too common with respect to economic demand and favors scarcer skills. Complex societies have evolved an ever-increasing division of labor, and a good deal of within-culture diversity is the result of division of labor. Intersociety trade is important in most human societies, leading to some division of labor between societies. If all else is equal, intersociety division of labor reduces diversity within societies and increases it between societies.

Trade aside, selection has complex effects on intersocietal cultural diversity. Much between-societies cultural diversity is due to cultures adapting to local conditions. By the Late Pleistocene, anatomically modern hunter-gatherers had spread to virtually all the world's habitable landmasses, developing a considerable diversity of subsistence strategies (Klein, 1999). Adaptive divergence is limited to the extent that societies in similar environments acquire similar adaptations (Johnson & Earle, 2000). But adaptive convergence is never complete, in part because environments are never exactly alike (Diamond, 1997) and probably in part because, like other complex design problems, the same functions can be realized more or less equally well by rather different arrangements (Boyd & Richerson, 1992a). Modern developed nations are a case in point. Despite much convergence, the G-8 nations (the world's richest economies) retain many distinctive differences in every aspect of their societies.

2. *Mutation*—Random copying errors are the ultimate source of variation in genetic systems, and random errors in cultural transmission play a similar role. Random errors tend to increase diversity both within and between cultures. However, as Henrich (2004) has shown, the errors that occur in cultural transmission also limit the diversity of culture by limiting the complexity of cultural traits. Complex, multi-component cultural traits are more likely to be transmitted with fatal errors. Small populations are more likely to lack the rare, highly skilled individuals who can recognize and re-

pair mistakes that develop as complex techniques are passed on, so, as mentioned earlier, the internal complexity of the culture that a population can sustain is limited by its size. Henrich reviews evidence that sophisticated watercraft was lost not only on Tasmania but also on other small islands in Oceania despite their importance to subsistence on the islands that retained them. Under these assumptions, errors will cause similar losses in different small-scale societies, reducing the scope for both between-group and within-group diversity. Techniques for storing cultural information outside the human mind, such as in texts or pictures, can counteract this effect, allowing small communities, such as a scientific subdiscipline, to maintain a large store of complex knowledge (Barth, 1990; Donald, 1991).

3. *Drift*—When cultural variants are rare or seldom used in a population, there is a random chance that they will be forgotten, creating the cultural analogue of genetic drift. Drift, therefore, is a force that decreases the total number of cultural variants. Since the effects of drift are random and affect different cultures independently, diversity between cultures is increased by drift. Again, techniques for creating external stores for cultural information counter the effect.

4. *Migration*—Spatial and social mobility cause people who have adopted different cultural variants to interact. This increases cultural diversity on the local level, because a mix of culturally different people increases the number of variants to which individuals in each group can be exposed, but it has no effect on the overall number of cultural variants that exist. The cultural diversity between groups is reduced by migration.

Conquest is a special case of migration; the military or commercial conquest of culturally different populations often leads to considerable reductions in diversity. This is well documented in the case of languages (Nettle, 1999). For example, the European conquest of the Americas led to the loss of most Amerindian languages to Spanish and English. Foster's (1960) study of the spread of other elements of Spanish culture to Latin America is a classic. A rather limited subset of Spanish culture penetrated the New World, giving Latin America anomalously low cultural diversity along many dimensions besides language. The ethnographic record suggests that such conquests are an ancient factor in patterns of diversity (R. C.

Kelly, 1985; Knauff, 1985). In the contemporary world, global mass communication makes European, and especially American, culture known to practically everyone.

5. *Bias on the part of the person acquiring the cultural information (learning biases)*—These selective forces in which individuals choose to adopt only some cultural variants, while ignoring or abandoning others, generally bring an overall decrease in the diversity of cultural variants.

- *Content-based bias*—This is highly analogous to natural selection. A new cultural variant that is widely perceived to bring practical benefits will be widely adopted, thus decreasing cultural diversity. An example of this is the widespread adoption in Europe of the potato as a staple crop during the 17th and 18th centuries. In many farming areas, choosing to plant potatoes over other crops increased the amount of food a peasant family could produce and the number of children it could successfully raise. In the case of the potato, the benefits were found to be exaggerated, and the farmers' dependence on the crop resulted in widespread famine when potato blight destroyed crops in the 19th century. Nevertheless, cultivation of the new crop had contributed to a rapid population expansion that prompted the migration of Europeans to other continents.

The diversity-reducing effect of content-based bias is mitigated by individual or group differences, both learned and genetic. If some groups of Europeans had been genetically ill-equipped to digest potatoes, then they would have not adopted the crop. Most human populations outside of the traditional dairying populations of western Eurasia and Africa cannot digest milk sugar (Durham, 1991). Thus, in eastern Eurasia an alternate technology based on soybean products evolved to fill roughly the same nutritional niche as milk. Much cultural diversity exists because literal and figurative tastes differ. Adaptive diversification and convergence proceed in roughly the same way they do with natural selection.

- *Model-based biases*—The imitation of individuals deemed by a group or subculture to be good models has the effect of decreasing diversity within that group, while increasing diversity between groups that have different criteria for choosing good models. The effect is, therefore, like that of conformity bias. Sym-

bolic systems are a very rich source of between-group diversity because of the arbitrary nature of symbols. High status can be symbolized by elaborate tattoos, as in Polynesia, or by “designer clothes,” as in today’s global commercial culture. Linguistic diversity is the most striking example.

- *Frequency-based bias*—Conforming to cultural norms by adopting the most common cultural variants in the cultural or subcultural group decreases diversity within groups and helps to maintain diversity between groups when migration occurs, because migrants begin to adopt the most common variants in the population they have joined.

6. *Communicator biases*—Individuals choosing the circumstances in which to display a cultural variant limits the number of cultural variants available for adoption. The effect varies, however, depending on the type of bias.

- *Situation-based bias*—Potential cultural models that regulate behavior depending on the social situation tends to reinforce ritual behavior, decreasing diversity within each social situation, but emphasizing differences between them. For example, “office worker behavior” may be similar in many different business organizations and quite different from the “factory worker behavior” in another part of the same organization. In both cases, the behavior displayed is likely to change substantially when individuals leave work to be with their families or take part in leisure activities. The long-term population-level effects of this have not been the subject of systematic investigation.

- *Observer-based bias*—Potential cultural models regulating their own behavior depending on who is watching is a barrier to the transmission of cultural variants and tends to decrease diversity within groups. For example, children mostly see adults displaying cultural variants that adults deem appropriate for them to see. However, this also tends to increase diversity between groups. Children then behave differently from adults, at least while adults are present. Again, the long-term population-level effects of the tendency of individuals to regulate their behavior in response to the observers present have not yet been subject to systematic investigation, however, so it is only possible to speculate on how this force may influence cultural evolution.

7. *Innovation*—The invention of new cultural variants is a force that increases diversity. New variants that are clearly superior to older variants may replace them, but often inventions increase choice and cultural complexity. For example, the invention of the automobile replaced bicycles and horses for many purposes, but the riding of bicycles and horses is still part of modern culture.

8. *Formal group decision-making processes*—When a group decision-making process is well supported by the group, it has the power to limit cultural diversity within the group and increase it between groups. Members cease to have the choice of whether to adopt a cultural variant. For example, if a decision to ban pornography is made and effectively enforced, the use of pornography cannot be adopted by group members. However, a group decision-making process is unlikely to maintain the support of the group if its decisions are unpopular with members, or if the decisions put the group at a disadvantage compared to other groups. Subcultures can often persist and even thrive in the face of considerable repression. For example, Handelman (1995) describes how the Russian Thieves’ World organized crime community persisted in the face of Imperial and Soviet repression. One might have thought that authoritarian societies that invest much in police “services” and have heavy punishment for deviance might at least be free of organized crime. However, the Thieves’ World rather successfully resisted suppression, much as the ethnically based prison and youth gangs thrive in the United States despite (or perhaps because of) long prison terms.

It may be the case that groups using similar group decision-making processes tend to make similar decisions. It is commonly alleged by some politicians, for example, that democracies are less likely to declare war. If this were the case, then finding effective means of group decision-making would have the effect of reducing cultural diversity between groups. Certain group decisions may support diversity. The most obvious would be decisions that specifically protect minority cultures. The U.S. Bill of Rights protects religion and speech, ensuring protections for many kinds of cultural variation. Swiss federalism provides for canton-level autonomy in many matters. Many group decisions have complex effects upon cultural diversity. Economic growth policies tend to bring modernity’s effects on diversity, reducing local

diversity in many aspects of culture, while increasing the diversity of occupations and spawning many medium-size subgroups, such as businesses and government bureaucracies.

REPRISE: EFFECTS OF MODERNIZATION

Modern communication and transportation technologies, and the development of global markets, have profoundly changed the social environments in which culture is propagated (Inkeles, 1983). By examining how these changes affect the balance of cultural evolutionary forces, we can estimate how these changes affect cultural diversity (Henrich et al., 2001; Shoumatoff, 2005).

In theory, modern communication could allow social influence to be centralized and the dissemination of cultural ideas to be dominated by a small number of powerful individuals or groups that could decide to suppress the dissemination of some cultural variants, while attractively presenting others. Even if such individuals had no malign intentions, their activities could, in theory, destroy diversity and create a homogenized global culture.

This is unlikely to be the case in practice, however, because whether a cultural variant is adopted or ignored depends on the decision-making processes in the minds of potential recipients of the information. Evidence suggests that increasing the means by which the information can be transmitted has little effect on these processes. For example, the wide-scale acquisition of mobile phone use behavior, which brought substantial changes to the lives of many people, did not occur immediately as a result of exposure to advertising and news of the new technology. The pattern of adoption traced the same S-shaped curve (Massini, 2004) as the adoption of hybrid corn among Midwestern farmers in the 1940s (Griliches, 1957), suggesting that the spread of mobile phone use largely took place by diffusion as nonusers modeled their behavior on those who had adopted the new technology. Their decisions were the result of some combination of model-based and frequency-based bias cultural transmission. Content-based bias undoubtedly also played a role. The rate of adoption was slightly influenced by variations in the cost of buying and using mobile phones, suggesting that at least some people partly based their decision on an analysis of costs and benefits.

Henrich (2001) has found that biased cultural transmission dominates in practically all cases of the diffusion of innovations.

Mass communication, therefore, may well hasten the spread of a useful new cultural variant at the *population* level, because it makes it possible to expose many people to the new cultural variant simultaneously, but *individuals* still go through the same process when deciding whether to adopt a new variant. This is substantially based upon observations of earlier adopters.

New technologies that threaten to reduce cultural variation may also provide means of preserving or increasing it. For example, random error in the transmission of cultural information (mutation) is a source of cultural variation that is potentially much reduced by computers, photocopiers, printers, and the equipment for audio and video recording and copying. Centrally planned educational syllabuses, textbooks, and standard exams attempt to ensure that all students in a population are exposed to more or less the same things in the same way. What consumers of information actually *learn*, however, cannot be controlled, and it may be that information reproduction technology actually *increases* the likelihood of errors in the transmission of cultural information. Cultural transmission occurs when a cultural variant is reproduced in a *human mind*, not on paper or disk. Simply presenting many people with many identical copies of accurately stored information does not ensure error-free transmission of the same cultural variant to every one of them. It fact, it vastly decreases the amount of information to which people can be exposed. Potential learners can choose where to direct their attention.

Although not decreasing the net amount of cultural variation, changes in social interaction can reduce diversity between groups and regions. This shift began with the development of agriculture. Pagel and Mace (2004) have suggested that human subpopulations continually secede and diverge from larger groups to better control some defensible resources. In a simple society of nomadic foragers, cultural divisions create geographical separation, because the physical environment is the source of the resources. The more resource-rich the physical environment, therefore, the larger the number of cultures it can support. The development of technologies that increase the resources extracted from the environment inevitably allow

a greater diversity of cultures to occupy a given area. The development of agriculture increased the carrying capacity of some habitats enough to allow the growth of population centers of unprecedented size and density. This brought changes in the pattern of cultural diversity, with different cultures and subcultures inhabiting the same geographical space.

Some diversity of social roles does exist within mobile foraging cultures, primarily based on age and gender (R. L. Kelly, 1995), but all members of a cultural group exploit the same habitat or habitats, so they must all acquire more or less the same knowledge and skills. In sedentary societies, members have more opportunity to invest time and resources in modifying their home environment, creating artificial habitat diversity within a geographical region and increasingly making their living by exploitation of a range of *culturally* created niches. Those exploiting the “farming” niche needed to acquire different knowledge and skills than tradesmen, artisans, and soldiers. Cultural divisions therefore develop between occupational categories. Just as those who share a niche in the natural environment share a desire to defend the physical resources present within their territory, those who exploit the same cultural niche share a desire to control access to the resources that their skills and knowledge allow them to acquire.

Modernization amplifies and extends the changes that began with the advent of agriculture. Before modernization, most people migrated as part of their family or social group. Modernization brings *individual* spatial and social mobility (Bongaarts & Watkins, 1976; Zelinsky, 1971). Individuals migrate to urban centers to work in factories and often leave their region or country of birth. Children attend school and have less exposure to the cultural variants of their parents and more exposure to nonfamily culture. In the terms developed by cultural evolutionists, oblique and horizontal transmission increases and vertical transmission declines.

The increasing inclination of Western mothers to return work soon after giving birth causes nonparental exposure to begin earlier in a child’s life. In many cases, this results in infants being exposed to cultural variants from nannies and day care assistants who are temporary or first-generation immigrants. Mass communication further increases the proportion of nonparental cultural trans-

mission. More and more of the cultural variants available to members of a modernizing society are transmitted between people who are not kin, friends, countrymen, or even acquaintances. Young people are therefore less likely to follow the ways of their parents and more likely to create novel recombinations of diverse cultural variants. As the modernization process continues, the choice of occupations, educational specializations, and ultimately leisure pursuits available to young people increases. Individuals whose genetic inheritance is very similar might end up with a very different cultural endowment.

One consequence of the decrease in interaction between kin that accompanies modernization may be the fundamental cultural change that is characteristic of modernizing societies; people begin to limit the number of children they produce and birthrates decline sharply (Newson et al., 2005). Social interactions between kin are more likely than interaction between friends or work colleagues to include encouragement or to reward behavior likely to lead to the expansion of the family (Newson et al., in press). In modern social networks, in which there is little contact between kin, the content of social influence is far less pronatal. Natural selection, therefore, favors people who have not embraced modernity, or who have adopted other cultural variants associated with modernity but not the belief that it is better to have a small family. Anabaptist populations, for example, have a high birthrate and are increasing rapidly because they enjoy the prosperity associated with life in modern North America but resist cultural influences from outside their kinship-based communities (Richerson & Boyd, 2005, Chap. 5).

The size of modern populations and complexity of cultures and subcultures sharing the same space, resources, and problems have forced increased use of formal group decision making. Councils and representative bodies are by no means an innovation of modern cultures and have been observed in foraging societies (Boehm, 1996), but as societies become more complex, increasingly sophisticated institutions are necessary to reconcile the interests of individuals and groups that have access to, or desire access to, the same space and resources. Individuals and groups that are culturally very different increasingly share problems and must agree on solutions. Inevitably the increased use of decision-making bodies reduces cultural di-

versity, because these bodies are authorized to limit the cultural variants available to the populations they represent.

The need to find compromises and to make decisions that can be justified to all interested parties influences the decision-making process and inevitably the decisions themselves. Judgments must appear rational and consistent, and (where possible) be supported by evidence and appeal to a set of values appreciated by all the interested parties. The success of a formal decision-making body depends on the extent to which the population approves of the choices it provides. One form of group decision-making process that is an innovation of modern societies is the survey or opinion poll, through which putative “decision makers” can be guided on the decision to make. How the various, formal decision-making processes might affect cultural change has not yet been studied by evolutionists.

The technological and social changes associated with modernization increase rather than decrease the range of cultural variants available for individuals to acquire. Paradoxically, this can give the impression of reduced cultural diversity. Although the choice is wide, the same range of choices is increasingly available all over the world, particularly in urban areas. The cultural institutions, practices, and values necessary to allow culturally diverse groups to cohabit contribute to this impression. There is cultural-evolutionary convergence on variants, such as convertible currencies, a publicly acknowledged criminal code with formal trials of those accused of transgressions, evidence-based decision making, tolerance of diversity, and respect for individual choice that make effective and peaceful transactions possible.

SUMMARY AND CONCLUSION

It is useful to think of culture as a collection of “cultural variants” maintained in the minds or records of members of a population. This is analogous to the genes—the collection of “genetic variants” maintained in the gene pool of a species. Cultural change occurs by a process of evolution, as described by Darwin, which is analogous to but different in detail from biological evolution. Darwinian theory and mathematical modeling tools used by population geneticists to understand changes in the gene pool over time can be used to understand and model cultural change.

It is transmission of cultural information from individual mind to individual mind that maintains culture variants in a population, and it is the increased adoption of some variants (including new variants) compared to others that drives cultural change. The adoption of cultural variants is not random; remembering a fact, developing an opinion, or learning a skill is the result of a conscious or unconscious decision by an individual. The pattern of adoption of cultural variants has been the subject of investigation by social psychologists, and the findings are consistent with humans having evolved psychological mechanisms that bias decision making to increase the likelihood of an individual acquiring useful rather than maladaptive cultural variants. At the population level, these biases can be seen as forces that influence the direction of cultural evolution. Our ability to understand cultural differences and change can be improved by systematic observations of the forces driving cultural evolution and the creation of testable hypotheses that predict outcomes as a result of social and environmental change. This creates huge scope for research in quantitative ethnography and cultural psychology. The topic may be almost endlessly complex, but it is correspondingly endlessly fascinating, and our understanding can improve with study.

Modernization brings rapid cultural change, and we have presented here a demonstration of how cultural-evolutionary theory can be used to examine how modernization affects cultural diversity. Although it is often suggested that modernization reduces cultural diversity, an evolutionary analysis suggests a more mixed picture. If “diversity” is defined as the number and variety of cultural variants available for individuals to acquire, modernization undoubtedly increases diversity. If, however, “diversity” is seen as regional differences in available culture variants, then it has decreased. In small-scale societies, the complexity and diversity of culture within societies is small, but the diversity between small, local groups is large. Waves of modernization over the last few thousand years have created complex cultures with substantial diversity within them, but they destroy much small-scale variation in the course of their expansion. The formation of intermixing cultural groups, which began with the advent of agriculture and creation of population centers, increases rapidly with modernization.

CHAPTER 19

Cultural Psychology of Moral Development

JOAN G. MILLER

Morality is central to culture. As noted by Shweder, “culture” involves “community-specific ideas about what is true, good, beautiful and efficient that are . . . constitutive of different ways of life, and play a part in the self-understanding of members of the community” (1999, p. 212). Whereas it is widely agreed that culture involves shared moral commitments (e.g., D’Andrade, 1984; Strauss & Quinn, 1997), the issue of whether morality is culturally variable remains controversial. The concern is raised by many psychological theorists that acknowledging cultural variability in morality leads to the stance of an extreme moral relativism, and that cultural approaches to morality embody passive views of the individual (e.g., Turiel, 2002). Work from the perspective of cultural psychology challenges this conclusion. Documenting qualitative cultural variation in moral outlooks, this work draws implications for expanding basic psychological theory in the area of morality, addressing challenges about how to understand moral development in ways that both avoid extreme moral relativism and embody a dynamic view of the individual and culture.

The goal of this chapter is to provide a critical analysis of research on culture and morality,

identifying contributions of work in this domain. The first section presents an overview of mainstream psychological theories of moral development, with a focus on understanding why, despite their attention to cultural issues, theorists in this tradition reject the idea of any significant cultural variation as existing in moral outlooks. This is followed by an overview of key theoretical assumptions of cultural psychology, as well as a review of empirical work documenting cultural variation in moral outlooks. In turn, the final section of the chapter identifies new directions for research on moral development.

APPROACHES TO MORAL DEVELOPMENT IN MAINSTREAM TRADITION

Psychological approaches to moral development tend to treat morality as based on criteria that individuals perceive to be above social consensus, rather than merely on rules, norms, or other societal standards. It is assumed that the issues individuals consider to be moral are concerns that they regard as involving right or wrong, and as going beyond what is merely normative or socially accepted. Thus, from this

perspective, it is recognized that morality transcends societal standards and differs from mere social conventions. However, although these assumptions about the formal criteria defining morality are widely shared, controversy exists concerning the content issues that individuals invest with moral force. Whereas it is assumed within work in cultural psychology that the content of morality shows significant cultural variation, the content of morality is assumed to be universal within mainstream psychological viewpoints.

Discussion below focuses on the theoretical models of moral development forwarded in the most clearly developed and influential mainstream psychological theories of morality: the cognitive-developmental framework of Kohlberg, the distinct domain perspective of Turiel, and the morality of caring framework of Gilligan. Although the theories differ in their views of the content of morality and of the ontogenetic processes through which morality arises, they share a stance of defining morality as emerging through developmental processes that do not depend on cultural input and of downplaying the role of culturally variable content assumptions as impacting on moral codes.

Cognitive-Developmental Model of Kohlberg

Kohlberg's cognitive-developmental model of moral development has been the most conceptually influential framework in the field, inspiring most of the later work that followed (Kohlberg, 1969, 1971, 1981). The model grounds morality in philosophical arguments that Kohlberg saw as providing an objective basis for morality and is distinguished by its formulation of a compelling stage model. Groundbreaking in its time and dominating research on moral development in developmental psychology for many decades, the Kohlbergian model offers a universalistic approach. Strikingly, however, this universalism is based, not on ignoring culture, but on rejecting, both on theoretical and empirical grounds, the validity of cultural approaches to morality.

Part of the Cognitive Revolution in psychology and drawing heavily on Piagetian theory, Kohlberg forwarded a model that offered a sharp break with the then-dominant behaviorist and psychoanalytic models of morality (e.g., Berkowitz, 1964; Eysenck, 1961; Freud, 1930). Piaget had rejected behaviorist and matu-

rial approaches because, in his view, they treat knowledge as merely a copy of information supplied by the environment. He furthermore assumed that cultural approaches resemble behaviorist perspectives in embodying a passive view of the child (Piaget, 1932, 1973). Kohlberg adopted these same assumptions, agreeing with the Piagetian premise that the active construction of knowledge is antithetical to cultural learning (Kohlberg, 1971).

However, beyond this concern shared by Kohlberg and Piaget that cultural approaches assume a passive view of development, Kohlberg raised additional concerns about the problematic stance of a relativistic morality that he felt inhered in giving weight to culture. Thus, he criticized the "relativist point of view" held by anthropologists as assuming "the validity of every set of norms for the people whose lives are guided by them" (Kohlberg, 1971, p. 159). Citing an argument by Brandt, he maintained that such a stance leads to the condoning of abusive practices merely because of their normative acceptability:

It does not follow directly from the fact that the Romans approved of infanticide and we do not, that infanticide was really right for them and really wrong for us or that it is neither right nor wrong for everybody. (Brandt, 1959, p. 84; cited in Kohlberg, 1971, p. 159)

Kohlberg also pointed to the logical contradiction of relativistic appeals for tolerance of other people's beliefs as a stance that treats the principle of toleration itself in nonrelative terms.

To construct a universalistic morality, Kohlberg grounded his theoretical model in logical arguments based on Western philosophical premises (Rawls, 1971). Drawing from the Kantian concept of the categorical imperative, Kohlberg argued for the necessity of excluding relationship-based and affective considerations from morality. In this view, to be moral, an outlook must meet the formal criteria of being universally applicable, prescriptive, and capable of being applied in an impartial and impersonal manner. Such a morality is seen as excluding any considerations that relate to one's social position or to any type of affective considerations.

The six-stage developmental sequence of moral development forwarded by Kohlberg

(1969) treats role-related and affective types of considerations as lower forms of reasoning that individuals emphasize at earlier, premoral levels of development. In this model, the most developmentally primitive stance forms the preconventional level, focused on affective and other self-interested concerns, including a stance of avoiding punishment (Stage 1) and of instrumental exchange (Stage 2). In turn, the developmentally more advanced conventional level encompasses relationship and role-related considerations, including a focus on social role expectations (Stage 3) and on the rule of law and other societal-level concerns (Stage 4). Finally, the developmentally highest level, the only level at which reasoning is considered fully moral in nature, includes both a stage focused on individual rights that have been agreed upon by the whole society (Stage 5) and a stage focused on self-chosen principles of justice, human rights, and respect for the dignity of individual persons (Stage 6). The methodology utilized in research on the Kohlbergian model involves presenting individuals with hypothetical moral dilemmas that embody justice issues and assessing individuals' open-ended reasoning in resolving these dilemmas. Although successful in evoking highly reflective moral reasoning, the emphasis in this methodology on the verbal articulation of responses introduces a complexity for children and other populations with limited education.

The Kohlbergian model has been subject to extensive cross-cultural testing that Kohlberg and his colleagues have interpreted as supporting the universality of the Kohlbergian claims, despite the consistent findings of extensive cross-cultural variation in the observed distribution of moral reasoning (Snarey, 1985). Thus, for example, in an early report of cross-cultural findings, Kohlberg (1971) noted that whereas most U.S. respondents by age 16 had reached the postconventional level of moral development, in both Taiwan and Mexico, the dominant form of reasoning reached by this age was only at the conventional level. This type of result showing that higher levels of moral development were only reached in sociocultural communities marked by characteristics such as Westernization, higher education, and urbanization was interpreted as evidence that particular environments are more stimulating than other sociocultural settings and thus push cognitive development faster and further.

This developmental perspective on cultural differences adopted by Kohlberg provided a framework for interpreting the marked cross-cultural differences in moral reasoning as reflecting variation in the individual's rate of development but not in the fundamental concepts that comprise morality. Although critics charged that the Kohlbergian scheme was biased in its grounding in Western liberal, secular cultural assumptions (e.g., Simpson, 1974; Sullivan, 1977) and may have been insufficiently sensitive to the adaptive demands of different sociocultural settings (e.g., Edwards, 1975; Harkness, Edwards, & Super, 1981) or to response biases linked to socioeconomic status (e.g., Buck-Morss, 1975), theorists in the Kohlbergian tradition remained unmoved by these critiques, finding the evidence of cross-cultural variation to be fully compatible with their claims of a universal developmental progression of justice morality (Kohlberg, Levine, & Hewer, 1983). As will be seen in the later discussion of research in cultural psychology, only when the fundamental conceptual assumptions of the Kohlbergian model were subject to a culturally based conceptual broadening were more fundamental cultural challenges to the Kohlbergian model articulated.

Distinct Domain Framework

The distinct domain framework developed originally by Turiel (1983, 1998a), but associated with a growing number of theorists (e.g., Turiel, Smetana, & Killen, 1991; Nucci, 2002; Smetana, 1995), challenges the developmental claims of the Kohlbergian model, while retaining its universalism. The Kohlbergian model portrays the development of moral understandings as involving a process of cognitive differentiation in which individuals hold one dominant form of understanding at any given time, with developmentally more adequate later understandings arising through transformation of developmentally less adequate earlier understandings. Thus, conventional understandings emerge as a replacement for preconventional understandings, and moral understandings emerge as a replacement for conventional understandings. Challenging this view, distinct domain theorists argue, in contrast, that social experience is always multifaceted, with different types of understandings applied to different types of social behaviors. Thus, rather than viewing one type of outlook as replacing an-

other over development, the distinct domain theory maintains that at any given point in development, individuals apply different forms of understanding to different types of social issues.

As in both Kohlbergian and Piagetian theory, theorists in the distinct domain tradition assume that morality centers on content issues involving harm, justice, and individual rights, and that moral development occurs through self-constructive processes that do not depend on cultural input. As in Kohlbergian theory, it is also assumed that cultural approaches to morality inevitably lead to an extreme moral relativism and are antithetical to the active construction of knowledge. In contrast to the Kohlbergian view, however, the self-constructive processes underlying moral judgment are seen as entailing relatively simple inductive judgments rather than the complex deductive judgments assumed within the Kohlbergian framework. It is assumed that issues involving harm and injustice are categorized as moral, issues involving social coordination, as social conventions, and issues that involve neither type of concern are categorized as matters of personal choice.

Methodologically, work within the distinct domain perspective utilizes simplified methodologies for assessing moral reasoning that uncover greater developmental competencies than are apparent with the Kohlbergian protocol (Turiel, 1983). Utilizing child-friendly testing procedures, the methodology focuses on the child's ability to distinguish between different types of social rules, rather than, as in Kohlbergian testing, on their open-ended response justifications. Thus, for example, to assess whether a child categorizes an issue such as hitting in moral terms, short-answer response questions may be asked to assess whether the child treats the rule against hitting as nonchangeable (e.g., "Would it be okay to change this rule?"), non-culturally-relative (e.g., "Would it be okay to have a different rule about this in another school?"), and nonlegitimately subject to regulation (e.g., "Is this the person's own business?").

Research by theorists in the distinct domain tradition has tended to focus on clear-cut "prototypical" issues and to uncover findings that individuals in all cultures have the ability to distinguish between issues of morality, convention, and personal choice, and that this ability is evident in children as young as preschool

age (Turiel, 1983, 1998a). Such findings are interpreted as supporting the model's claim that judgments of harm and injustice take a universal form that is unaffected by cultural influences. As I discuss later, however, work within cultural psychology has challenged this conclusion in examining a broader range of types of issues. This latter work, as will be seen, not only provides evidence that conceptions of morality extend beyond issues of harm and justice but also that judgments of harm and justice vary depending on culturally variable content assumptions.

Morality of Caring Framework of Gilligan

The morality of caring framework developed by Gilligan (1977, 1982) offers a compelling cultural critique of Kohlbergian theory, as well as of related assumptions in the distinct domain perspective, both in its argument for the need to treat morality as extending to issues of caring, rather than as limited to the avoidance of harm and injustice, and in its assertion that perspectives on morality are gender-related. However, although conceptually broadening the scope of the moral domain in these ways, the framework retains a universalistic emphasis. The morality of caring is formulated in culturally invariant terms and issues of gender variation treated as fundamentally the same across all cultures.

From the perspective of the morality of caring framework, the argument is made for the need to treat issues of caring in fully moral terms rather than to limit the scope of morality to the prohibition-oriented issues of justice. Drawing on psychodynamic formulations and attachment theory, the perspective maintains that the distinctive socialization experiences of males and females lead to the development of contrasting senses of self and morality (Gilligan & Wiggins, 1988). In identifying with their mothers and in having experiences in family interaction that emphasize interpersonal responsiveness, girls are seen as developing a connected sense of self and an associated morality of caring. This sense of self and morality, however, becomes problematic at adolescence, when the girl finds that it conflicts with the autonomous sense of self valued in the larger culture. In contrast, although males are seen as attached to their mothers, they are assumed to identify with their fathers. Desiring to overcome the inequality that they experience in re-

lation to their fathers, males are seen as developing an autonomous sense of self and associated morality of justice.

The model assumes that although there exist two rather than only one type of moral perspective (i.e., moralities of both justice and of caring), the form of these perspectives is culturally invariant. As Gilligan argues, "All people are born into a situation of inequality and no child survives in the absence of adult connection. Since everyone is vulnerable both to oppression and to abandonment, two stories about morality recur in human experience" (Gilligan & Wiggins, 1988, p. 281). The universality of morality is assumed to reflect the universality of gender-related developmental processes, as well as the cross-culturally common experience of gender bias. Any observed cross-cultural variation in the moralities of caring and of justice is assumed to represent only a minor difference in relative emphasis and not in the basic form of either type of morality.

In testing the claims of the morality of caring framework, Gilligan and her colleagues typically tap moral reasoning in the context of real life rather than hypothetical situations and employ interpretive data analysis techniques that involve the qualitative assessment of open-ended interview data. Support for the claim of gender differences was uncovered in early research undertaken by Gilligan and her colleagues (Gilligan, 1982; Gilligan, Ward, & Taylor, 1988). However, subsequent studies by a broader range of investigators have tended to find little or no evidence of gender variation (Thomas, 1986; Walker, 1984; Walker, Pitts, Hennig, & Matsuba, 1995).

The universality of the morality of caring framework has been assumed rather than subjected to explicit cross-cultural empirical testing. Although some studies have been conducted by Gilligan and her colleagues with ethnic minority populations within the United States (e.g., Bardige, Ward, Gilligan, Taylor, & Cohen, 1988; Ward, 1988), no known work undertaken in this tradition has tested the assumed cross-cultural universality of this form of morality. The studies conducted with ethnic/minority populations have in some cases called into question claims about the morality of caring being gender-related (Stack, 1986), as well as, most recently, highlighted the links drawn between caring and social justice among African American respondents (Walker & Snarey, 2004). However, there has been no direct chal-

lenge to the morality of caring itself. This result reflects the tendency for research to focus only on any references to caring rather than to consider qualitative cultural variation in the nature of caring responses. As will be seen, in tapping caring in ways that are more sensitive to the contrasting cultural meanings underlying caring responses and to contextual variation in care-based reasoning, work in cultural psychology reveals the existence of qualitatively variable forms of the morality of caring.

Summary

Drawing initial inspiration from the seminal theoretical model of Kohlberg, mainstream psychological theories in recent years have increasingly embraced the distinct domain perspective, a viewpoint that retains the focus on the morality of justice but treats justice understandings as coexisting with understandings of social conventions and personal issues. Arguments forward by Gilligan for the existence of a morality of caring are also highly influential in contemporary work, although such a morality generally is no longer considered to be gender related but rather is seen as embraced by both males and females. Differing in their focus, these various mainstream perspectives share a universalistic emphasis that treats culture as incompatible with the requirements of morality.

KEY ASSUMPTIONS OF WORK ON MORAL DEVELOPMENT WITHIN CULTURAL PSYCHOLOGY

This section presents a brief overview of some of the key theoretical premises of cultural psychology and of the underlying assumptions of work on moral development from a cultural psychology perspective. Consideration of these assumptions makes clear respects in which a cultural focus embodies the constructivism and contextual sensitivity of mainstream psychological models of morality, while giving greater weight to cultural influences on the content of moral codes.

Mutual Constitution of Culture and Psychological Processes

Cultural psychology has at times been characterized as a subfield or area of specialization in psychology, and this type of view may be inad-

vertently implied by the present contrast between the “mainstream” tradition of work on moral development and perspectives within cultural psychology. This terminology, however, is used only to distinguish approaches characterized by different theoretical assumptions about the role of culture in basic psychological theory, and not to distinguish different areas of specialization or fields of study. Work within cultural psychology is defined fundamentally by its conceptual commitments to a view of culture as central in human experience and cuts across all areas of psychology rather than representing a subfield of the discipline.

The core of cultural psychology is the premise that cultural and psychological processes are mutually constitutive (Cole, 1990, 1996; Markus, Kitayama, & Heiman, 1996; J. G. Miller, 1997, 1999; Shweder, 1990; Shweder & Sullivan, 1990, 1993). It is not only assumed that culture depends on communities of intentional agents but also that psychological processes require cultural experience for their developmental emergence. With the exception of certain innate propensities that are evident early in infancy, the emergence and maintenance of most psychological processes are seen as dependent on cultural input. Cultural meanings which involve processes of mediation and internalization, are viewed as impacting on individuals’ psychological understandings and affecting their cognition and behavior:

Cultural, institutional, and historical forces are “imported” into individuals’ actions by virtue of using cultural tools, on the one hand, and sociocultural settings are created and recreated through individuals’ use of mediational means, on the other. The resulting picture is one in which, because of the role cultural tools play in mediated action, it is virtually impossible for us to act in a way that is not socio-culturally situated. (Wertsch, 1995, p. 90)

From this perspective, it is recognized that, although children assume an active role in making sense of their experience, this experience is, in part, culturally patterned. As Bruner (1973) notes, whereas it was recognized during the Cognitive Revolution that individuals go beyond the information given in contributing meanings to experience, the essential role of culture in this meaning-making process was not fully apparent:

What was obvious from the start was perhaps too obvious to be fully appreciated. . . . The symbolic systems that individuals used in constructing meaning were systems that were already in place, already “there,” deeply entrenched in culture and language. . . . When we enter human life, it is as if we walk on stage into a play whose enactment is already in progress—a play whose somewhat open plot determines what parts we may play and toward what denouements we may be heading. (Bruner, 1990, pp. 11, 34)

Within cultural psychology, it is assumed that whereas individuals’ understandings of the world and participation in it are mediated by cultural symbols, there is no one-to-one relationship between cultural meanings and individual understandings (J. G. Miller, 1997). In contrast to the claims made by various theorists in the cognitive-developmental and distinct domain traditions (Turiel, 2002), cultural-psychological approaches do not treat the individual in passive terms or assume that there exists a one-to-one mapping between cultural meanings and individual understandings. Rather, cultural psychology embodies an active view of the agent, while also treating this agent as fundamentally socioculturally embedded rather than as a pristine processor of information (Schwartz, 1981).

Dynamic Views of Culture and Psychology

From an ecological perspective, culture is conceptualized in functional terms as adapted to the objective affordances and constraints of different environments (Berry, Poortinga, Segall, & Dasen, 1992; Bronfenbrenner, 1979). In an early, highly influential example of this type of model, in the Six Culture Project, cultural practices are treated as functionally related to the objective requirements set by different ecological conditions, with psychological processes seen as mediating between the culture and the physical environment (Whiting & Whiting, 1975). Thus, linkages in this investigation were demonstrated among rich natural ecologies, societies with complex social structures, and child-rearing practices that emphasize competitiveness. Ecological approaches to culture are essential in calling attention to the contrasting adaptive demands of different settings, thus challenging a view that treats the contexts for human development as universal.

Although not downplaying the importance of ecological views of culture, work in cultural psychology emphasizes the need to understand culture also in symbolic terms (Geertz, 1973; Shweder & LeVine, 1984). From such a perspective, culture is seen as a system of symbolic meanings that are embodied in artifacts and practices, and that bear an open rather than fully determinate relationship to objective constraints (Shweder, 1984). Culture is also understood as reflecting, in part, nonfunctional considerations rather than being exclusively functionally based (LeVine, 1984). Such a perspective implies that cultural values and activities cannot be explained exclusively by reference to objective ecological conditions. To give an example, research indicates that Japanese educators tend to consider the preschool practice of having many children assigned to a given teacher as functional in providing children with experience in and promoting their knowledge about being good members of a group (Tobin, Wu, & Davidson, 1989). This symbolic value, however, is less central in U.S. contexts in which preschool educators tend to consider it beneficial to have fewer children assigned to a given teacher, so that the children may be accorded more individual attention and more opportunities to exercise individual decision making. Thus, whereas both types of preschool classroom practices may be considered adaptive, the basis of their functionality cannot be understood merely by reference to objective constraints, such as school resources, but requires also taking into account nonfunctional values, such as pedagogical viewpoints, related to goals for the children's development.

Within cultural psychology, not only is culture seen as affecting the meanings of contexts, and the practices through which contexts are structured, but psychological processes themselves are also recognized as being contextually dependent (J. G. Miller, 1997, 2002). It is assumed that cultural influences on psychological phenomena depend on contextual considerations and should not necessarily be assumed to be highly generalized. Thus, it must be understood, that because a psychological process is in part culturally constituted does not imply that the psychological process, or that any observed cross-cultural variation, is contextually invariant. Rather, the argument is for the need to give weight *both* to culture, as shared meanings and practices, and to context, as objective

affordances and constraints, in psychological explanation rather than to reduce one type of consideration to the other.

Conceptions of the Moral

In terms of assumptions related specifically to understanding moral development, theorists in cultural psychology acknowledge commonality and variability in conceptions of both moral and nonrational influences on moral outlooks. These assumptions give rise to a culturally broadened view of diversity rather than to an extreme moral relativism (Miller, 2001).

Formal versus Content-Based Definitions of the Moral

Work in cultural psychology distinguishes between formal and content-based definitions of the moral. Issues of morality are seen as distinguishable from issues of mere social convention by formal criteria such as their perceived generalizability, impersonality, unalterability, and ahistorical qualities (Pool, Shweder, & Much, 1983; Turiel, 1983). Thus, a rule seen in moral as opposed to conventional terms is assumed to apply in all similar social contexts rather than, as in the case of convention, to depend on local customs and norms. Equally, what is moral is considered to be impersonal in the sense that it does not depend on an individual or society recognizing it as such. Whereas issues of morality are seen as nonalterable by social consensus and as historically invariant, issues of social convention are seen as alterable by social consensus and as historically contingent. Areas of behavior that are perceived to be beyond the scope of legitimate social regulation and, thus, considered issues of neither morality nor social convention, are understood as matters of personal choice.

Note that in distinguishing between different types of social understandings on the basis of these formal criteria, researchers in cultural psychology and in the mainstream traditions of work on moral development are rejecting a purely emotivist stance on morality, as might be found in certain behaviorist approaches (Berkowitz, 1964), or a purely conventional stance on morality, as might be found in certain social-psychological work that makes no distinction between morality and mere normative conformity (e.g., Darley & Pittman, 2003; Tay-

lor, 2003). Although the influence of affective factors on moral reasoning is not denied (Haidt, 2001; Kagan, 1984), what is moral is considered by the individual to be based on criteria that go beyond mere self-interest or instrumental gain.

However, whereas mainstream and cultural-psychological approaches agree on similar formal definitions of the moral, cultural-psychological approaches treat the relationship between the form and content of morality as potentially culturally variable, whereas it is assumed to be cross-culturally invariant within mainstream approaches (J. G. Miller, 2006; Shweder, 1982). This, then, constitutes the most central point of contrast between the two traditions. Mainstream theories assume that issues of harm, justice, and welfare have the same fundamental meaning and are categorized in the same terms universally. In contrast, work from a cultural psychology suggests that the content invested with moral force extends beyond the issues of harm, rights, and welfare concerns, and that the same types of content issues may be categorized in different terms depending on culturally variable meanings and practices.

Importance of Nonrational Considerations

Reflecting their cognitive-developmental roots, mainstream psychological theories of moral development emphasize the rational nature of moral judgment. Moral reasoning is portrayed as fundamentally similar to other types of cognitive inference, in being based on deductive or inductive processing of information. Thus, if individuals draw different moral inferences based on the same information (e.g., if it is morally acceptable in one cultural population to have an abortion and in another it is not), this difference is likely to arise ultimately from variation in individuals' knowledge about the nature of the harm involved and to be resolvable, at least potentially, by individuals obtaining more scientific facts about the situation (Turiel, Killen, & Helwig, 1987). From this perspective, moral outlooks are considered to be ultimately reconcilable (i.e., it is assumed that if all individuals had the same information and were able to process this information cognitively in an equally accurate and nonbiased manner, their understandings of the "facts" of situations would be the same, as would their moral judgments (Turiel et al., 1987).

Whereas work within cultural psychology acknowledges both the rational and affectively based inference processes that inform moral judgment, attention is also given to the nonrational judgments that enter into weighting of information and that invariably reflect considerations of value rather than purely reflections of the "facts" of given situations. To give an example, whether abortion is considered a moral violation or a matter of the woman's personal discretion depends in part on culturally and subculturally variable conceptions of which entities in the world are to be considered persons and entitled to protection from harm (Shweder, Mahapatra, & Miller, 1987). This delineation of personhood (i.e., the question of when to consider human life as beginning) represents a matter of value that can never be decided based on biological considerations alone. Likewise, in another example, the criteria that underlie the moral appraisal that it is appropriate for parents to read their 10-year-old child's report card without prior permission but not to read their child's diary reflect culturally variable conceptions of what constitute "territories" of the self (e.g., Do they extend to one's mail?) and of what constitutes harm (e.g., Does reading this particular information constitute a violation of the child's privacy or an appropriate expression of concern?). The types of cultural meanings that inform these judgments embody nonrational assumptions that cannot be merely controlled or held constant when evaluating differences in moral outlook. Thus, to attempt to hold them constant when appraising cultural differences in moral outlook, a stance recently advocated by theorists in the distinct domain tradition, would mean adopting a stance that bleaches culture of its meaning (J. G. Miller, 2006).

Although much of the resistance to culture in mainstream approaches to moral development stems from a concern that cultural approaches invariably lead to extreme forms of relativism, this is not the stance adopted within cultural psychology. As noted, the type of position adopted in work on moral development within cultural psychology does not eschew comparative evaluation of cultural practices or equate moral acceptability with the social acceptance of particular practices. Rather, it recognizes that the cultural meanings given to particular practices affect their implications and must therefore be given greater, though still not absolute, weight in evaluating their moral status.

RESEARCH ON CULTURE AND MORAL DEVELOPMENT

Research on culture and moral development centers not merely on assessing the universality of psychological theories of moral development but on expanding the psychological constructs and process explanation invoked in understanding moral outlooks. As will be seen, this work highlights the need to expand present psychological models of morality to recognize qualitative variability in basic moral constructs and outlooks.

Justice Reasoning

Issues of justice have a central role in all psychological theories of morality, with the moral status of justice unchallenged even in theories such as that of Gilligan, which sees the scope of morality as expanded to encompass other types of concerns, such as caring. The central role of justice in any morality is equally not called into question in work in cultural psychology. Rather, on an abstract or formal level, the ideas of both justice and harm are assumed to exist in all moral codes, with the idea of justice seen as the abstract rule of treating like cases alike and the idea of harm as that of avoiding harm (Shweder et al., 1987). However, as cultural theorists have noted, at this abstract level, justice and harm are compatible with a wide range of cultural diversity in moral outlooks, because cultural communities fill in notions of harm and justice in markedly culturally variable ways.

Commonalities

The universality of at least of some moral concern with justice is seen in the mention of justice concerns in moral reasoning early in development, and in at least some commonality in justice reasoning in concrete cases. Thus, cross-cultural commonality tends to be observed in justice judgments in cross-cultural research that utilizes content issues involving “prototypical” cases in which there is considerable cross-cultural agreement about the meaning of the situations portrayed (Turiel, 1983). This can be seen, for example, in control issues included in cross-cultural research that involve issues such as theft or arbitrary assault, which are portrayed as undertaken in a voluntary and intentional way under decontextualized circum-

stances that include no mention of any alternative motivation or meaning to the behavior. Thus, for example, both Indian and U.S. adult populations have been shown to agree that taking another person’s property without their permission represents a moral violation that involves justice violations and includes a violation of property rights (J. G. Miller, Bersoff, & Harwood, 1990; Shweder et al., 1987). Notably, awareness of justice violations is documented in research that utilizes similar prototypical vignettes with young children. Thus, in research involving children as young as 3 years old both in the United States (Smetana, 1981; Smetana, Schlagman, & Adams, 1993) and in different Asian cultures (Song, Smetana, & Kim, 1987; Yau & Smetana, 2003), children identify acts involving arbitrary assault and violation of property rights as justice violations that have moral rather than merely conventional status.

Research of this type supports the idea that justice concerns form part of morality universally. However, it does not indicate that, universally, justice concerns will invariably be accorded the same priority as other types of competing moral issues, that individuals will be held accountable to the same degree cross-culturally for justice breaches, or that the same issues will be conceptualized as involving justice concerns. It is in these areas of instantiating justice judgments in the concrete contexts of everyday moral reasoning that cultural variation in justice morality is shown to exist.

Variation in Priority Given to Justice Relative to Competing Moral Issues

In terms of priority given to justice judgments compared to other types of competing issues, cross-cultural research indicates that even in cases in which there is substantial cross-cultural agreement about the moral status of the justice issue involved, cross-cultural variation may result from differential priority being given to justice issues compared to other salient, competing moral concerns. Such a tendency may be seen, for example, in the following qualitative response given by a respondent to a Kohlbergian hypothetical dilemma that involved the issue of whether a son should let his father spend money for his own personal uses that the son had earned, and that the father had promised to let the son use to pay for attending camp. A Kenyan respondent is responsive to

the justice issue embodied in the vignette (i.e., the breach of a promise by the father) but gives priority to the son's duty to be responsive to his father's wishes and authority:

[If a father breaks his word], it will cause hatred because the son will be angry, saying, "I wanted to follow my own intentions, but my father cheated: he permitted me and then refused me." . . . So it is bad. . . . [However,] the one for the son is worse. Imagine a child disobeying my own words, is he really normal? (Edwards, 1986, p. 425)

The Kohlbergian scoring protocol, it may be noted, was not sensitive to this type of differential weighting of justice and competing moral concerns, and would have scored this as a nonmoral conventional stance. This type of stance, failing to appreciate the moral character of conflicting concerns, may have contributed to the skewed distribution of moral reasoning observed cross-culturally (Snarey, 1985).

Other evidence that there may be relatively greater priority given to interpersonal considerations compared to competing justice concerns in collectivist cultures is supported by experimentally controlled research that presented samples of U.S. and Indian adult and child populations with hypothetical conflict situations in which fulfillment of a justice issue conflicts with fulfillment of a competing interpersonal responsibility (J. G. Miller & Bersoff, 1992). An idiographic procedure was utilized in constructing the conflict situations to ensure that individuals viewed the individual justice and interpersonal breaches as equivalent in their seriousness and as tapping a range of issues, from major life-threatening concerns to minor issues. There was a common trend to give priority to the justice issues in the case of the life-threatening breaches (i.e., that pitted taking a life against saving a life). However, in a pattern congruent with the cross-cultural Kohlbergian trends reported earlier, marked cross-cultural differences were observed in the case of the non-life-threatening breaches. Thus, the Indian respondents tended more frequently to give priority to the competing interpersonal obligations than did the U.S. respondents. For example, whereas all of the U.S. respondents judged that it was morally wrong to steal a train ticket, even if this was the only way to fulfill the interpersonal responsibility of attending a best friend's wedding, a majority of the Indian re-

spondents judged that it was morally required to participate as planned in the wedding, even if this meant having to engage in the justice breach of stealing the ticket.

While supporting the universality of a moral concern with issues of justice, this research challenges claims that justice issues invariably take priority over competing moral concerns, an assumption that has been made in past theorizing based on the Kantian notion of perfect versus imperfect duties (Gert, 1988; Kant, 1797/1964; Urmson, 1958). From this latter perspective, justice is considered a "perfect" duty that may be fully realizable, in that it involves prohibition-oriented concerns (i.e., not to violate another's rights or to harm another). In contrast, helping and issues of family and friendship obligations are considered "imperfect" or "superogatory" concerns. The latter are considered desirable to undertake, but because of their positive orientation (i.e., calling for positive responsiveness to someone else's needs), they are too unbounded in scope to be fully realizable and must therefore always be somewhat delimited in scope. The present evidence highlights the need to recognize that whereas this type of formal distinction may be drawn between negative versus positive duties, the cultural meaning given to these two types of issues is crucial in how they are weighted in moral judgment, and not merely their status as positive versus negative obligations (J. G. Miller, 1991).

Variation in Weighting of Contextual Factors

Cross-cultural research on social attribution has documented marked cross-cultural differences in social inference. Thus, it has been demonstrated that there tends to be a greater emphasis on explaining social behavior in terms of dispositional traits of the person in individualistic cultures, whereas in collectivist cultures more weight is given in social attribution to social role relations and other contextual factors (Cousins, 1989; J. G. Miller, 1984; Shweder & Bourne, 1984). In terms of moral reasoning, these cross-cultural differences related to folk theories of the agent's relationship to the surround translate into variation in judgments of moral accountability or responsibility.

Judgments of accountability are presupposed in moral reasoning, in that they bear on the intentional nature of behavior. The domain of rule-governed behavior involves voluntary

action in which the agent is judged to have sufficient control over his or her behavior to be held accountable for performing it. From this perspective, an agent cannot be held accountable for a behavior that is a mere occurrence or involuntary event; only if it is judged that an agent could have acted otherwise or prevented a particular behavior can he or she be held accountable for having engaged in this behavior. Thus, as research has shown, persons tend to be judged less responsible for a given behavior to the extent that the behavior is understood to be unintended, the agent is seen as lacking the capacities to understand the consequences of his or her behavior or to control its execution, or the behavior is seen as under the control of situational influences (Darley & Zanna, 1982; Fincham & Jaspers, 1980; Heider, 1958).

Research evidence suggests that in tending to view behavior as more situationally influenced than U.S. populations, Indians tend more frequently to treat contextual factors as extenuating circumstances that reduce agents' accountability for justice violations (Bersoff & Miller, 1993). Thus, it has been shown that Indian adult and child populations more frequently absolve agents of accountability for what they perceive to be harmful or unjust behavior to the extent that this behavior is undertaken either under emotional duress or in the context of agent immaturity. For example, whereas both Indian and U.S. respondents agree that breaking into a locked house constitutes a moral violation, Indians more frequently than Americans maintain that agents should not be held morally accountable for such a breach if the agent had been frightened by an unexpected noise.

Variation in Definitions of Harm and Injustice

Perhaps most fundamentally, cultural variation in justice reasoning reflects the contrasting cultural theories of the person, of social relations, and of their interrelationship that affect how harm and justice are defined in concrete cases. Notably this variation is not just a matter of individuals having different available information but of contrasting definitions of personhood and harm that cannot be merely adjudicated by reference to the "facts" of situations.

Within Hindu Indian culture the persons seen as entitled to protection from harm extends to all forms of life (Vasudev & Hummel,

1987). Rather than a matter of mere personal choice, refraining from eating or otherwise harming animals is considered a moral and not merely a personal issue. Likewise, in other cases, the domains of the self that are seen as entitled to protection from harm may be drawn more broadly in collectivist than in individualistic cultures, resulting in acts that have a moral status in individualistic cultures not seen as entailing issue of harms or rights violations in collectivist cultures. Thus, for example, with respect to issues of family inheritance, in assuming that females should be accorded equal status as males, U.S. adults consider an inheritance practice that disadvantages the female to be a violation of her rights (Shweder et al., 1987). In contrast, in treating male–female relations in more differentiated terms, Indian adults consider it appropriate and thus not a moral violation for females to have lesser inheritance than males. It may be further noted that within cultures of honor, such as found in certain communities within the U.S. South, conceptions of personhood are so intertwined with social reputation that harm to reputation tends to be perceived as inseparable from harm to the self (Cohen & Nisbett, 1997; Vandellos & Cohen, 2003).

Interpersonal Morality

Interpersonal morality pertains to responsibilities that exist to meet the needs of others and is therefore a type of "positive" morality that contrasts with the "negative" or prohibition-oriented morality of justice. Whereas justice morality involves refraining from acts of harm or injustice, interpersonal morality involves showing positive responsiveness to the needs of others. Interpersonal responsiveness has always been considered an aspect of morality, because it concerns issues of welfare; however, at least within the Kantian tradition that informs the work of theorists such as Kohlberg and Turiel, it has been assumed to have a superordinate or discretionary status rather than the fully obligatory character of justice morality (Kahn, 1992).

As noted earlier, in forwarding her model of a morality of caring, Gilligan (1982) challenged these Kantian assumptions and argued for the need to recognize caring as a qualitative, distinct form of morality that differs from that of justice but is fully moral in character. Thus, she maintained that the morality of car-

ing is not subordinate to that of justice. She also argued that the morality of caring is based on a type of affective commitment or "co-feeling" that is oriented toward welfare concerns and is not vulnerable to self-serving and non-welfare-oriented emotions.

I mention the contributions of cultural research to demonstrate that moralities of caring take distinctive forms, and that the form of the morality of caring identified by Gilligan and her colleagues represents a culturally distinctive perspective grounded in the individualism of U.S. culture. Strikingly, this work also provides direct insight into the nature of caring responses among U.S. populations, suggesting that morality of caring responses are more contingent than assumed.

To assess the perceived moral status of caring, research conducted among U.S. and Indian adult and child populations tapped perceived responsibilities to meet the needs of others in cases involving low sacrifice or cost to the helper, and varying role relationships and levels of need (Miller et al., 1990; see also J. G. Miller & Luthar, 1989; J. G. Miller & Bersoff, 1994, 1995). In both cultures, helping tended to be seen as highly desirable and as a perceived responsibility. Among the U.S. respondents, the dominant tendency was to treat helping as a matter for personal decision making, whereas among Indian respondents, helping tended to be seen as an issue that is legitimately subject to social regulation. The trends observed among the U.S. respondents call attention to respects in which the approach to caring adopted in Gilligan's model embodies a voluntaristic approach to interpersonal responsibilities that is consonant, at least in this respect, with the aretaic model of helping assumed in the Kantian tradition, and that is in accord with the emphasis on personal freedom of choice in U.S. culture. In contrast, they point to the existence in India of a tendency to accord interpersonal responsibilities a more obligatory moral status, one that accords it the same status as issues of justice, a pattern predicted by neither the aretaic model of the Kantian framework nor Gilligan's portrayal of the morality of caring.

Gilligan herself emphasized the freely given nature of interpersonal responsiveness in the morality of caring, viewing caring responses as based not on role obligations but on affectively grounded personal commitments, providing a reliable basis for moral commitments that is

not affected by nonmoral emotions. A cross-cultural study conducted among U.S. and Indian adults, utilized a between-participant manipulation to assess the impact of personal affinity and liking on perceived interpersonal responsibilities (J. G. Miller & Bersoff, 1998). Both U.S. and Indian respondents judged that moral responsibilities of parents to their young children were unaffected by such nonmoral affective considerations (i.e., the responsibility to meet a need of one's child is unaffected by how much personal affinity and liking one has for the child). However, in the case of adult siblings, friends, and even adult troop leaders to their child Scouts, U.S. adults judged that the responsibility to help was less when the relationship involved low personal affinity and liking compared with high personal affinity and liking. Thus, for example, U.S. respondents judged that a man had less moral responsibility to help his brother move into a new apartment if the man and his brother shared few common tastes and interests, and were not affectively close, compared with a situation in which they shared many tastes and interests, and had a warm and affectionate relationship. In contrast, the moral responsibility to help was not found to be contingent on such nonmoral considerations among the Indian respondents. These results suggest that the morality of caring as it exists among middle-class European American respondents is more contingent on nonmoral affective considerations than previously assumed, and, in this respect, somewhat vulnerable to the unreliability assumed by Kantian theorists to inhere in any affectively based morality. In contrast, the results suggest that the type of role-based perspective emphasized among middle-class Hindu Indian respondents is less contingent on nonmoral affective preferences.

Research conducted among U.S. populations of different religious backgrounds extends this work by suggesting that the pattern observed among U.S. respondents may reflect, at least in part, the value placed within Christianity on acting in accord with one's mental states (Cohen & Rozin, 2001). It was documented that, compared to Jewish respondents, Christian respondents make a more negative appraisal of the moral character of a hypothetical agent who behaves in ways that are responsive to the needs of his elderly parents whom he dislikes. These findings, which were demonstrated in other types of moral appraisal as well, not only

point to possible within-culture sources of variation in interpersonal morality but also identify some of the specific ways that Christian doctrine may have impact on the results observed in the cross-cultural investigation by J. G. Miller and Bersoff (1998), a study undertaken among a predominately Christian U.S. population.

More generally, the consistent pattern of cross-cultural differences observed in these various studies highlights the need to broaden the theoretical framework of Gilligan to take into account the observed cross-cultural variation. The responses observed among the U.S. and the Indian respondents both represent moralities of caring and encompass what theorists have characterized as types of *Gemeinschaft* concerns (Snarey & Keljo, 1991). However, whereas the approach captured in Gilligan's theoretical model privileges a voluntaristic approach to caring of an agent acting outside of role obligations, the approach captured in the work described earlier in India privileges an agent attuned to what are perceived to be natural duties associated with his or her social roles. This insight led to the proposal for expanding the theoretical constructs invoked to understand interpersonal morality, with the type of approach captured in Gilligan's model termed an "individually oriented" perspective and that observed in India termed a more "duty-based" perspective (J. G. Miller, 1994). Notably, the point of these conceptual labels is to call for an expansion of theory in this area and not to make assertions about uniform differences in moral orientation (J. G. Miller, 2006). In arguing that the morality of caring can take a "duty-based" form, no claim is being made that Indians always emphasize duty in moral reasoning, just as when Gilligan argued for the existence of a "morality of caring," she was not claiming that women in all cases emphasize caring in moral reasoning.

Although the available research to date is limited, evidence suggests that modes of caring found in other collectivist cultures differ in distinctive ways from both the morality of caring framework identified among U.S. respondents and that observed in the Indian research discussed earlier. To give some examples, work has uncovered among Japanese populations an emphasis on an approach to interpersonal morality that centers on issues on *omoiyari*, or empathy within one's ingroup (Shimizu, 2001). For example, such a stance is reflected in the

following response of an adolescent boy who does not report a case of vandalism by another student to the teachers; the boy takes such action in empathizing with the student's desire to retain a supportive relationship with his mother, the school nurse—a relationship that would be disrupted by such a report:

You see if I became their enemy (by accusing them), they would feel uncomfortable to see my mother. . . . So although they destroy school property, I would feel bad for them if they lost someone with whom they could talk about their problems. (Shimizu, 2001, p. 463)

In turn, work with Chinese populations illustrates an approach to interpersonal morality that privileges what is perceived to be the innate, affectively grounded moral tendency of *jen*, "the deep affection for kin rooted in filial piety and extended through the family circle to all men" (Dien, 1982, p. 334). This can be seen, for example, in the invocation of the concept of *jen* by a Chinese respondent in reasoning about the Heinz dilemma:

Even though the law did not set limit to the price of the drug, the druggist should not set the price so high because the druggist should have the feeling of distress at the suffering of others. He knows pretty well that the drug is used to cure people in danger, and if the price is so high, the poor people couldn't afford to buy it and would therefore lose their lives. So, the price should not be set so high based on *jen*. In addition, in making the drug, the druggist should hold a "doctor-with-a-parental-heart" attitude. Otherwise, the social consequences are likely to be disastrous. (Ma, 1997, p. 107)

Although this type of response would be scored at the conventional level in the Kohlbergian approach, as critics have pointed out and as argued here, it represents a type of alternative, communitarian postconventional morality.

Moralities of Divinity

Treating morality as secular in nature, the dominant psychological theories of morality assume that religious concerns have no role in morality. Within the mainstream frameworks, religion is excluded from morality, because it is seen as based on faith rather than on rationality. Although it is empirically observed that spiritual concerns are mentioned in open-ended reasoning, such concerns are considered to be

merely conventional rather than moral in nature. Cultural research demonstrates, in contrast, that spiritual concerns are integrally related to concerns with justice and caring, and are therefore the core to lay conceptions of morality.

Evidence for this claim may be seen, for example, in research on moral exemplars. Thus, in an in-depth qualitative study of the perspectives of individuals who identified as having shown extraordinary moral commitment, Colby and Damon (1992) observed that many of these individuals attributed their value commitments to their religious faith. Such a stance is illustrated in the following explanation given by a respondent who ascribes the years she devoted to caring for the poor to her conversion to fundamentalist Christianity: "I didn't know how I was doing it or why, but I know the Holy Spirit was leading me, saying, 'You have to help them, you have to help them'" (p. 354). As reflected in this response, many individuals attributed their stamina in being able to make the type of personal sacrifice entailed in living morally exemplary lives to their faith and saw serving God as part of the justification for their actions. Similar results have been observed in the case of populations who maintain a predominantly secular outlook. Thus, for example, Walker et al. (1995) found that concerns with religion, faith, and spirituality commonly informed the lay conceptions of morality held by adolescents and adults from the Vancouver area of Canada, a region that is highly secular. In this investigation, religion was observed to provide justifications for a morality built on ideas of justice and welfare, including concerns that focused on issues of reward and punishment, such as fear of eternal damnation; concerns that appeared to include some conventional elements, such as the importance of church and fellow believers; and concerns that involved moral principles such as *agape* love.

Spiritual outlooks have been shown to motivate not only commitments to moralities based on justice or caring but also to entail distinctive epistemological assumptions that impact on how issues of justice and caring are understood at different ages. Such trends were documented, for example, in a study examining the responses of Nepalese Buddhist monks to the Kohlbergian Heinz moral dilemma (Huebner & Garrod, 1991, 1993). Reflecting outlooks framed by Buddhist conceptions of karma, at

younger ages, respondents centered on the negative karma that would ensue from Heinz stealing the drug. As a young adolescent argued, "If you create negative actions (bad karma), then you will become sick or die and when you die, then you will go to the animal realm or to the hell realms . . . or you will be born into very bad future lives with much sickness and no money" (1993, p. 180). In contrast, at older ages, karma entered into moral judgments in affecting the reasons why life is to be valued. Thus, in assuming that all beings continue to exist in some form endlessly, an older adolescent justified saving Heinz's wife's life out of concern for her contributions to society:

If the person dies, then that person will no longer be around. He will go on to another existence, but maybe he will be an animal or in another part of the world. Anyway, he will never be exactly the same again. This is the way it is, and so we must protect people from dying. If it is for two more years, or even as short as three months, this person can still do some good things. He can help another person. (Huebner & Garrod, 1991, p. 181)

In these responses, the central concept is not one of a perceived right to life, as observed typically among respondents from a Judeo-Christian background, but rather the unique qualities distinguishing different lives.

Importantly, cultural evidence also demonstrates that spiritual outlooks not only support moralities of justice and of caring but also constitute their own distinctive form of morality. Thus, Shweder, Much, Mahapatra, and Park (1997) established that there exist three and not merely two, broad forms of moral orientation: (1) an ethics of "autonomy" that involves issues of harm, rights, and justice, and that has been the center of both Kohlbergian research and that in the distinct domain tradition; (2) an ethics of "community" that involves responsiveness to the needs of others, and that has been the focus both in Gilligan's morality of caring model and in more cultural approaches to caring; and (3) an ethics of "divinity" that has tended to be considered exclusively a conventional type of orientation. The morality of divinity involves concerns with issues such as the sacred order, sin, purity, pollution, and sanctity that bear on protection of the human soul from spiritual degradation and on promotion of spiritual refinement. Evidence for the

existence of this ethic may be seen in themes that were spontaneously mentioned in reasoning about everyday behavioral events among an orthodox Hindu Indian sample and a secular U.S. sample (Shweder et al., 1997). In certain cases, concerns with divinity were common across the two cultural populations, with both U.S. and Indian respondents raising concerns primarily involving divinity in the case of the issue of incest. In other cases, the concerns tended to be culturally variable, with, for example, the secular U.S. population tending to consider eating beef as involving the absence of harm and the orthodox Hindu Indian population centering on the spiritual degradation that would ensue from such behavior. The morality of divinity has also been shown to be distinguishable from the moralities of autonomy and of community in terms of its emotional meanings. Thus, research conducted among U.S. and Japanese college students demonstrates that disgust is associated with violations of purity-sanctity, a central concern in the morality of divinity, whereas anger is linked to the individual rights' violations associated with the morality of autonomy, and contempt is linked to the violation of communal codes in the morality of community (Rozin, Lowery, Imada, & Haidt, 1999).

Work on themes of divinity also highlights the need to understand morality as extending beyond issues involving harm or welfare and demonstrates that perceptions of harm or welfare are culturally variable. In this regard, research conducted among a U.S. and a Brazilian population of lower socioeconomic status demonstrates that issues perceived to involve extremely disgusting or disrespectful actions, such as using the national flag for a bathroom rag or eating the family dog, are perceived as moral violations, even though such actions are regarded as principally involving concerns related to divinity and not harm (Haidt, Koller, & Dias, 1993). Thus, within the Brazilian population, moral judgment was more closely predicted by asking whether the respondent was "bothered" personally by the action than by asking whether anyone was harmed. Work by Jensen (1997, 1998) has further documented that whether or not harm is even seen as existing in a given situation depends on spiritual outlooks. This trend is illustrated in work comparing moral judgments of the orthodox Hindu Indian practice of *sati*. Whereas orthodox U.S.

respondents treated such behavior as an issue of moral harm, many of the orthodox Indians viewed it as virtuous behavior. As one orthodox Hindu informant commented:

Sati is morally right. . . . The wife dies with her husband in order to (preserve) her chastity and (show) her devotion to her husband. (Jensen, 1998, p. 101)

Work of this type notably highlights the need to recognize that whether or not harm is even perceived to exist depends in part on culturally and religiously based value commitments.

Summary

Cultural work demonstrates that marked cross-cultural variation exists in justice reasoning that reflects contrasting weighting of competing moral and nonmoral concerns, and culturally variable assumptions concerning the nature of persons, harm, and territories of the self entitled to protection from harm. This work also documents that forms of interpersonal morality are culturally variable; indeed, the framework proposed by Gilligan is itself a culturally bound model. Culturally variable forms of interpersonal morality differ in important respects, among others, such as their emphasis on personal choice, contingency on nonmoral considerations, and weight accorded to affective considerations. Importantly, cultural work is also highlighting the need to expand the scope of the moral domain to encompass concerns involving divinity. Such concerns constitute a distinctive form of morality that embraces conceptions of spiritual concerns that transcend issues of harm.

NEW DIRECTIONS

In terms of promising new directions, cultural work on moral development is further examining the nature of moral reasoning in everyday contexts, exploring issues of power dynamics and culture conflict, and contributing to an understanding of the developmental processes through which moral outlooks emerge. Select examples of this work are briefly discussed below as I highlight some of the new theoretical insights and methodological approaches that distinguish work in this area.

Morality in Everyday Contexts

In examining moral development in relation to a wider range of everyday situations, cultural work is contributing to further conceptual broadening of the scope of the moral domain. One example of this type of approach is found in a recent series of studies that examined reasoning about real-life ecological issues, such as the 1990 Exxon *Valdez* oil spill, among children of different sociocultural backgrounds and different everyday relationships to the natural environment (Howe & Kahn, 1996; Kahn, 1997, 1998, 1999). Age-related changes were observed among U.S. children, with second graders tending to emphasize a "homocentric" form of reasoning that focuses on implications of harm to the ecology relative to human welfare (e.g., that polluting nature would get people sick), and fifth-grade and eighth-grade students placing greater emphasis on "biocentric" reasoning that treats nature itself as having moral standing or an intrinsic right to be protected from harm. In contrast, homocentric forms of reasoning tend to be emphasized among children from the Brazilian Amazon. Providing evidence to suggest that universally moral and not merely conventional reasoning is applied to protecting the natural world from harm, this work also highlights the varied sociocultural processes that impact on children's outlooks. Thus, whereas the perspective of the U.S. sample appears to reflect in part the emphasis placed on ecological concerns in the curriculum of U.S. schools and popular culture, the outlooks of children from the Brazilian Amazon appear to stem, at least in part, from individuals' sense of being more dependent on nature for their immediate physical survival.

In another example of approaches to understanding morality in everyday contexts, an ethnographic study examined the processes by which youth organizations create moral experiences that are instrumental in participant's adaptation in the larger community (Heath, 1996). Norms that develop in such organizations promote moral values, such as a sense of fair processes, as well as family-like relationships of caring. Such outlooks are reflected, for example, in the everyday conversations among members of an all-male, African American inner-city basketball team in reflecting on how they saw their coach as getting them to do what was considered right. Work of this type points to the value of understanding moral values as

they emerge in everyday behavioral interaction and conversational interchange, rather than conducting studies focused explicitly on moral reasoning tasks.

Power Dynamics and Culture Conflict

In terms of new directions, cultural work also focuses on integrating a concern with cultural meanings and practices, and a concern with power dynamics. It is recognized that cultural meanings and practices may in some cases constitute instruments of domination, in which groups in subordinate positions suffer discrimination and have unequal access to resources (e.g., Abu-Lughod, 1993; Appadurai, 1988; Turiel, 1998b, 2002). However, cultural also emphasizes work that relationships of unequal power need to be understood in the context of culturally variable meanings and practices.

In the area of dissent, research demonstrates that cultural practices are framed in ways that take into account distinctive cultural emphases; thus, they do not in all cases privilege what is assumed in mainstream psychological theories of morality to be the universal moral value of individual equality. This type of trend was observed, for example, in a comparative study examining conceptions of everyday family roles and of feminism among samples of middle-aged women from Japan and the U.S. (Schaberg, 2002). Although the Japanese women expressed dissent with the gender role practices of their society, their concerns did not map directly onto the concerns with seeking greater freedom of choice and equality expressed by U.S. respondents. Valuing reciprocal interdependence in family relationships, the Japanese women criticized the family role expectations of their society as insufficiently flexible and called for greater accommodation in gender role expectations. However, they rejected the egalitarian model of marital relations emphasized by U.S. respondents. The Japanese respondents also forwarded a moral critique of what they viewed as the individual-centered and, in their eyes, somewhat selfish stance of U.S. feminism, and called for a form of feminism that, differing from that emphasized within the United States, entailed a greater commitment to social activism and contributing to the community.

In another example, an ethnographically based sociolinguistic study of Hindu Indian family life likewise documented respects in

which dissent tends to be framed in culturally distinctive ways that may give priority to social hierarchy rather than treat all persons as morally equal (Much, 1997). Such a trend may be illustrated in the example of an adolescent son in a Brahmin family who temporarily stopped wearing the holy symbol of the Sacred Thread. The son's reported motives were to challenge the moral meanings given to that symbol and to express his own personal view that wearing such a symbol represented merely an unimportant matter of social convention rather than a moral duty. However, in framing dissent in this way, the son notably did not call into question more fundamental commitments of his cultural community to the principle of hierarchy and to the importance of caste identity.

These same types of concerns with attending both to power dynamics and culturally variable meanings is also evident in work examining culture conflict in the context of immigration (Shweder, Minow, & Markus, 2002). This work, like that preceding it, focuses on the challenge of identifying standards for moral appraisal that, while being sensitive to issues of harm and abuse, recognize that their identification must proceed in culturally sensitive ways. In this regard, as Shweder, Markus, Minow, and Kessel (1997) have pointed out, problems arise when the legal system and other public institutions enforcing particular U.S. outlooks on values such as equality, child rights, and so on, end up overriding the contrasting outlooks and everyday practices of immigrant populations. In examining this type of issue, Shweder (2002) critically examined the meanings associated with a practice, such as female genital alteration, that, while treated as a universal issue of harm by various feminist scholars and governmental institutions, is invested with cultural meanings and embodied in everyday cultural practices that give it value as a sign of female identity and maturity. In other examples, Kim and Markus (2002) critically examine the cultural emphasis on verbal expression in particular U.S. mainstream cultural contexts, which gives rise to cultural practices that may infringe on what may be seen as a "freedom of silence" in immigrant groups that place a greater value on nonverbal modes of communication.

Notably, work in this general area of power dynamics and culture conflict is of value in addressing not only this central theoretical challenge of how to integrate a concern with cultural meanings and power dynamics in moral

appraisal of cultural practices but also the question of moral relativism that has been central in psychological work on moral development. It argues for the need to recognize the complex, yet necessary, questions that arise in moral appraisal of cultural practices. Embodying what might be characterized as a pragmatic rather than extreme form of moral relativism, this type of cultural psychology stance does not eschew comparative cultural appraisal but maintains that such appraisal must proceed with as complete as possible an understanding of local cultural viewpoints, including that of the observer. As Shweder comments:

Cultural psychology fully acknowledges that there is no way to avoid making critical judgments about good and bad, right and wrong, true and false, efficient and inefficient. . . . Any culture deserving of respect, must be defensible in the face of criticism from "outside." . . . One of the distinctive features of cultural psychology is that it is willing to try to make that defense, representing the "inside" point of view in such a way that it can be understood, perhaps appreciated, or at the very least tolerated from an "outside" point of view. (2000a, p. 216)

The resultant stance calls for a more pluralistic view of cultural diversity than that embodied in the mainstream perspectives on moral development in psychology, or in many contemporary public institutions. It acknowledges the existence at an abstract moral level of moral universals, including concerns with "justice, beneficence, autonomy, sacrifice, liberty, loyalty, sanctity, duty" (Shweder, 2000b, p. 164), while also recognizing that these goods are instantiated in culturally distinctive ways and cannot be maximized simultaneously.

Enculturation and Moral Development

Finally, another important new direction for work on moral development is to contribute to an understanding of the processes through which moral meanings are embodied and communicated in everyday practices. This work increasingly not only focuses on discourse practices as contexts for child socialization but also attends to language use and normative shifts that impact on the changing moral outlooks of adults.

Work with child populations is calling attention to the role of discourse practices as contexts in which children come to understand, as

well as to participate in creating, shared moral outlooks that are salient within their cultural communities. In early groundbreaking work in this area, Much and Shweder (1978) documented that children tacitly display, as well as come to develop, their ability to distinguish between different types of rules as a function of how they and others in their social environments respond to their behavior. Thus, kindergartners and their teachers offered distinctive types of justifications to breaches of different types of social rules. Both children and teachers tended to respond to breaches of social conventions with statements concerning the applicability of the relevant rule. For example, a child defended his violation of the rule that children were to play outside by citing his cold as a plausible exception to the rule—"My mother said! I just got a sore throat!"—only to be rebuffed by a teacher who offered an alternative interpretation of the prevailing rule—"Well, if you can't go out, then you stay home because you're sick" (Much & Shweder, 1978, p. 21). In contrast, children responded to breaches of moral rules, a type of rule that is considered absolute, in ways that either denied that the act occurred or that redefined the act to make the agent nonblameworthy. Thus, for example, a child accused of stealing a peer's chair responded that because the chair was empty, she did not steal it, she merely "sat in it" (p. 37). Notably, this type of conversational interchange, with its opportunities for feedback and negotiation, functioned in a tacit way that conveyed powerful culturally variable moral messages, even though it was not viewed by any of the participants as involving issues of morality.

Cultural work is also focusing on how everyday socialization practices in the family and larger community embody particular moral values. Thus, for example, recent sociolinguistic work among families from Taiwan has documented an emphasis on disciplinary practices that communicate a moral sense of shame (Fung, 1999; Fung & Chen, 2001). This may be seen in the following example of a mother and older sister's verbal shaming responses to a 3-year-old child who has committed the breach of approaching the researcher's camcorder. The mother threatens to ostracize and withdraw love from her child, commenting, "We don't want you; you stand here. Mama is mad. Look how ugly your crying will be on tape"—a stance underscored by the 5-

year-old sister joining in with the chant, "Ugly monster, ugly monster" (Fung, 1999, p. 193). This type of moral emphasis notably is also evident in other everyday socialization practices, with Taiwanese mothers using personal storytelling as an opportunity to communicate moral lessons through spontaneously narrating examples of children's past transgressions, a trend not observed among European American mothers, who tend more frequently to use such interaction as an opportunity for entertainment and affirmation of the child's sense of self and promotion of their self-esteem (P. J. Miller, Wiley, Fung, & Liang, 1997). More generally, cultural work is pointing to the role of culture in assigning children to different everyday socialization contexts that affect their moral outlooks. Thus, for example, Edwards (1985) has pointed to the role of everyday experiences in sibling caregiving in various African rural communities as opportunities for the socialization of responsibility, whereas cross-national comparisons have pointed to the role of voluntary work commitments for adolescents in promoting a sense of civic responsibility (Flanagan, Bowes, Jonsson, Csapo, & Shblanova, 1998).

Notably, work by Rozin (1999) on "moralization" examines processes by which affective preferences are converted into moral commitments among adult and not merely child members of a culture. Thus, Rozin traces how common cultural practices, such as cigarette smoking or even overeating, that may be associated with negative affective reactions such as disgust, can take on moral overtones for individuals through not only rational reflection but also a range of societal practices that call negative attention to such behavior, such as a cigarette tax, initiating scientific inquiry to uncover new information about processes that affect the behavior and the implementation of new legal regulations. Such processes of cultural change in the perceived moral status of particular behaviors can occur relatively rapidly, with the moralization of attitudes toward smoking occurring across three generations of Americans within a 20- to 40-year period, and morally coloring people's perceptions (Rozin & Singh, 1999). Thus, in a striking illustration of such an effect, U.S. college students tend to judge people who eat primarily high-fat diets to be less considerate than people who eat primarily fruits and vegetables (Stein & Nemeroff, 1995).

Summary

In terms of new directions, research on moral development is increasingly examining moral outlooks reflected in a wide range of real-life issues and everyday cultural settings. Integrating a concern with power dynamics with an attention to cultural meanings and practices, this work provides insight into processes of resistance and dissent, as well as issues of cultural conflict. New process accounts that are also being developed not only highlight the everyday practices and modes of social interaction that impact on children's developing moral outlooks but also provide insights into the affectively and culturally grounded processes by which moral outlooks change at a societal level that affects the outlooks of adults.

CONCLUSION

Research on moral development in cultural psychology highlights the need to expand contemporary mainstream psychological theories of morality, to make them more culturally inclusive, and to pay increased attention to the role of cultural meanings and everyday practices in the developmental emergence of moral outlooks. Rather than leading to an extreme form of moral relativism, work in this tradition underscores the importance of becoming more aware of the discretionary aspects of one's own cultural outlooks and of appraising alternative cultural commitments in ways that are appreciative of their coherence and sense. Generative in nature and increasingly addressing real-world applications, work on moral development in cultural psychology underscores the inseparable interrelationships between culture, morality, and lived experience.

CHAPTER 20

Situating the Child in Context

Attachment Relationships and Self-Regulation in Different Cultures

GILDA A. MORELLI
FRED ROTHBAUM

01.23.97 I am on a forest trail somewhere in the Ituri Rain Forest.¹ I am about a half a kilometer from Oboobi's camp and still I can hear shrieks of delight and hilarity as Efe men, women, and children prepare for what promises to be a night's worth of dancing at a local village. Everyone is celebrating a good rice harvest after a long hunger season. I know what to expect—women braiding hair and body painting anyone who asks, children practicing their dance steps, little ones wearing newly woven waist belts. What I didn't expect however was Kamisiku wearing a coveted shirt I gave to my friend Oboobi for this event. A bit surprised and maybe even a little bit angry, I asked Oboobi why Kamisiku had my shirt on. "Well," she replied, "she asked for it, and I couldn't deny her." But I said, "Now you'll go to the dance mbuchi" (in this instance meaning without a top to wear).

A few months later I sit with my husband under the stars enjoying the quiet that comes with darkness. So the rustling of leaves on the forest path comes as a surprise because it heralds a late night visitor. "Hodi," we hear, "usiangopa, mihaiko balozi" (Hello, don't be afraid, I am not

a spirit). Standing in the forest opening is Oboobi carrying a 20 liter container of palm oil and 10 kilograms of plantains (a goodly amount of desirable food). As she sits, Oboobi tells us of her good luck getting the food and asks if we would store it for her so she doesn't have to share it away with the other families in her camp.

Sharing is an assumed part of Efe life; it is part of what it means to be an Efe. Infants' experiences with sharing begin as soon as they are born, with camp members participating in their care. But, what is sharing? Is Oboobi acting out of obligation when she gives her shirt away and out of choice when she hides her food? Is the latter but not the former an autonomous action?

We start our chapter with Oboobi and the decisions she makes because they crystallize for us some of the thorny issues we consider in this chapter on attachment and self-regulation—issues of autonomy, internalization, and integration. These issues are closely tied to cultural differences in "healthy" development and "ma-

ture” ways of being in the world—fundamental concerns of this chapter.

Much of the research on attachment relationships and self-regulation builds on longstanding philosophical and theoretical traditions that prioritize the individual and the psychological processes of autonomy and internal cohesion (of which internalization and integration are the basis).² This theoretical legacy may be one reason why the antecedents of attachment relationships and of self-regulation—sensitive and responsive parenting—are similar, and why attachment and self-regulation lead to similar forms of later social competence (Miller, 2004). We do not doubt that these relations exist—at least for children growing up in communities that emphasize autonomous and internally cohesive ways of being in the world. However, in communities that emphasize other ways of being, antecedents and consequences may be different.

In this chapter we examine traditional accounts of attachment relationships and self-regulation in infancy and early childhood, as well as the experiences that foster their healthy development. Of primary interest is whether personal qualities such as autonomy and internal cohesion are important to the development of these psychological processes in people everywhere. We begin with a brief review of self-determination theory, because the psychological needs described by this theory (e.g., autonomy), as well as the process of developing autonomous forms of motivation (internalization and integration), are also cornerstones of the development of healthy attachment relationships and self-regulation. These Western-oriented traditions consider the self as agentic—an organizer of action and an integrative center of experience (Ryan, Kuhl, & Deci, 1997; Sroufe, 1996), internally controlled, and relatively unchanging across contexts. We next present a view on self-systems prevalent in non-Western communities that takes into account ways of being a person in the world that emphasizes qualities such as harmony and interdependence rather than autonomy and independence. What is important to this self is the self-in-context, and we consider the implications of this self-system for the psychological processes associated with attachment relationships and self-regulation, as well as the care experiences underlying their development. We end with a consideration of self-coherence and its relation to different notions of the self.

TRADITIONAL (WESTERN) THEORIES

Self-Determination Theory

What motivates people to carry out activities that—unlike exploration and novelty seeking—are not inherently or intrinsically satisfying? Why, for example, does a child give up her chair to a visitor, only to be left sitting on the floor? Why does a father use the little money he has to send his youngest son but not his oldest daughter to school? And why does a mother participate in genital cutting ceremonies to mark her daughter’s transition to adulthood? Self-determination theory addresses these questions.

Scholars working in this tradition believe that behavior is governed by external forces (the child might be punished if she did not let the visitor sit in her chair) or by personal volition (a child explores the environment because she wants to and chooses to do it). What distinguishes motivations along this continuum is the extent to which regulations are perceived as autonomous (Ryan & Deci, 2000a, 2000b). Self-determined regulations are freely chosen (internalized), fully integrated with other aspects of self, and experienced as authentic. On the other hand, regulations that are neither internalized nor integrated are a “controlled regulation . . . executed without being processed, coordinated, or endorsed by self” (Ryan et al., 1997, p. 707).

The need for autonomy, one of three universal needs posited by self-determination theorists, is best met in infancy and early childhood by caregivers who are appropriately contingent and receptive to their child’s signals; who structure and support their child’s endeavors in nonintrusive, unobtrusive, and fittingly challenging ways—following the child’s lead and fostering her sense of control and competence; who respects the child as a separate person with a will of her own; and who are warm and positive in their involvements. Grolnick and Ryan (1989) consider as exemplars of good parenting adults who value autonomy as a goal first and foremost, even at the expense of obedience and conformity; who rely on encouragement, praise, and reasoning to motivate children; and who are nondirective, preferring not to impose their will—including when children are in problem-solving and decision-making situations. When the need for autonomy is met, the person is more integrated intrapsychically (actions, thoughts, and feelings originate from self and internally cohere) and socially (Deci & Ryan, 2000).

There is a great similarity between self-determination theory and traditional accounts of attachment relationships and self-regulation in the prioritizing of personal agency, control, and internal cohesion, and in the qualities of care important to the development of these processes. The need for autonomy lies at the heart of all three theories.

Attachment Theory

05.16.96 *I am within meters of Afukbe's camp, and as is customary I announce my arrival with a chorus of hosis and greet people by shaking their hands asking while doing so if they have "beaten the morning"—unashinda. As I approach the chief's family, I see that his daughter is there with her toddler son. The toddler is clearly alarmed by my approach, but still his mother stretches out his arm and hand to allow me to shake it. However, as she does so, he digs in his heels, arches his back, and lets out a howl that rivals any I've heard before. The camp is utterly amused by this and begins to tease the child as he takes refuge behind his mother's back, dragging her breast with him. I am nonplussed. The Efe often get children to do things by telling them that the "white woman" is going to take them away if they don't, and I have sent many an unfamiliar child galloping into the arms of someone they know, tears streaming down their faces. I sit next to the chief, and watch amusedly as the toddler first peeks at me with breast in mouth, and slowly comes out from hiding to sit on his mom's lap. His mom takes the opportunity to tell him how I gave his grandfather medicine when he was sick, shows him the shirt I brought to welcome him, and asks him to greet me. His mom again stretches out his hand, and this time he allows me to shake it.*³

Attachment theory is concerned with a child's developing sense of self, other people, and relationships (Sroufe, 1996; Weinfield, Sroufe, Egeland, & Carlson, 1999), and it is psychology's most influential theory of relatedness. Confidence in self, what to look forward to from others, and the capacity for close relationships develop during the first year of life, based on a child's history of experiences with the people who care for him. These experiences, and the beliefs and expectations that develop from them, are represented by the child as "internal working models" (Bretherton, 1992). Early care experiences also play a role in the regulatory abilities the child develops, and together the child's internal working model and regulatory abilities form the basis for how well

he or she functions now and later on in life, both personally and interpersonally (Sroufe, 1996).

The core tenets of attachment theory originate in the work of Bowlby. He focused initially on the protective functions of the attachment system that promote infant survival (in order to reproduce). Accordingly, attachment system behaviors consisted of "any form of behavior that results in a person attaining or maintaining proximity to some other clearly identified individual who is conceived of as better able to cope with the world. It is most obvious whenever the person is frightened, fatigued, or sick, and is assuaged by comforting and caregiving" (Bowlby, 1988, pp. 26–27). However, Bowlby, along with Ainsworth and others, increasingly recognized the importance of broadening the function and set goal of the attachment system beyond infant survival and proximity to include the support of the infant's innate drive for exploration and mastery of the inanimate and social world made possible by "felt security" (Ainsworth & Bowlby, 1991).

Ainsworth's contributions to attachment theory included the concept of secure base, maternal sensitivity to infant signals, and patterns of infant attachment relationship; she also developed a procedure to test empirically assumptions related to attachment theory (Bretherton, 1992). This procedure, known as the Strange Situation, assesses individual differences in infants' relationships with their caregivers when stressed (Ainsworth, Blehar, Waters, & Wahl, 1978). Particular attention is paid to how well infants organize their attachment and exploratory behaviors when reunited with their caregiver after a short period of time alone or with an unfamiliar person (secure base phenomenon, see below). Infants who respond to their caregiver positively upon her return and who are able to use their caregiver as a base from which to explore the environment are characterized as being secure in their relationship. Insecure infants, in contrast, do not seek contact with their caregiver on her return (avoidant) or they are not able to become calm in her presence (ambivalent), and they do not use their caregiver as a secure base.

Attachment Relationships and the Secure Base from Which to Explore

Attachment theory places great importance on the child's ability to explore the environment

and aspects of the child's relationship with caregivers that makes this possible. Exploration with the support of caring others is one way the child is able to gather information about her inanimate and social environment and develop mastery over it. This mastery is important to the child's developing sense of self as competent and autonomous.

Exploration in and of itself does not promote autonomy in the child; the quality of the child's attachment relationship must be considered as well; in fact, it is the balance between exploration and attachment that matters. Healthy autonomy develops when the child is able to use his caregiver as a "secure base" from which to explore the environment, because he feels sufficiently protected and comforted by her presence. Children who do not experience this felt security—who neither view their caregiver as someone they can trust nor themselves as worthy of support—are not able to achieve the same confidence in their mastery of the environment, in themselves, and in others (Weinfield et al., 1999).

The attachment and exploration systems work in tandem, balancing one another, with activation of one reducing activation of the other (Ainsworth et al., 1978; Bowlby, 1982). Together they function to keep the infant out of harm's way and to enable him to explore the environment when all is safe. Although at any moment attachment and exploration are in opposition, over time they are complementary, and "infants who are effectively dependent will become effectively independent" (Weinfield et al., 1999, p. 76). As Bretherton writes, "Confidence in the mother's physical and psychological availability appears to lay the groundwork for autonomous exploration and problem solving, coupled with the expectation that help will be forthcoming when needed" (Bretherton, 1985, p. 21).

Sensitive Care and Security of Attachment Relationships

The ability of children to organize their attachment behaviors to balance their need for protection and felt security with their need for exploration, mastery, and autonomy relate to their history of care. The aspect of caregiving receiving the most attention is a mother's sensitivity and responsiveness to her infant and young child (Ainsworth et al., 1978; de Wolff & van IJzendoorn, 1997).

Bretherton (1987) described *sensitivity* as "maternal respect for the child's autonomy" (p. 1075) and three of the four scales developed by Ainsworth (1976) to evaluate caregiving emphasize autonomy supporting practices. For example, Ainsworth included in her description of the acceptance scale a mother who "values the fact that the baby has a will of its own, even when it opposes hers, . . . finds his anger worthy of respect, . . . [and] respect[s] the baby as a separate, autonomous person (p. 4). She noted in her cooperation scale that the "mother views her baby as a separate, active autonomous person, whose wishes and activities have a validity of their own. . . . She avoids situations in which she might have to impose her will on him" (p. 4). Finally, for her sensitivity scale, Ainsworth stated that "it is a good thing for a baby to gain some feeling of efficacy. She nearly always gives the baby what he indicates he wants" (pp. 3–4). This conceptualization of sensitive and responsive caregiving is still the "gold standard" in the field.

Competence and Attachment Relationships

Attachment theorists maintain that sensitive and responsive caregivers foster children's confidence to act effectively and autonomously both in early childhood and later in development. Children with different care histories fall short of developing the qualities that foster personal and interpersonal competence.

Research linking attachment security and competence support this claim, although the strength of the association between the two is modest. Thompson (1998) suggests that lack of theoretical clarity is partly responsible for this modest relation; attachment relationships should not foreshadow all aspects of later competence. He argues that there is little theoretical reason to expect a child's attachment relationship to predict later cognitive ability, but there is every reason to expect it to predict later aspects of social and emotional competence that relate to a child's representation of self, others, and relationships.

Children with secure attachment histories, compared to their insecure age mates, display more confidence and self-esteem, persistence in problem-solving tasks, and mature forms of exploration (Cassidy, 1988; Cassidy & Kobak, 1988; Grossmann, Grossmann, & Zimmermann, 1999; Matas, Arend, & Sroufe, 1978; Nezowski, 1983, cited in Wienfield et al.,

1999; Sroufe, Fox, & Pancake, 1983). Children with insecure attachment histories not only score lower on all of these measures but also higher on measures of other behavior problems. They are more likely to seek the attention and the physical closeness of adults at the expense of peer relations and to rely extensively on these adults for help.

Children with secure histories also enjoy more positive relationships with their parents and peers than do young children with insecure histories. These children experience more mutually rewarding experiences with their mothers (Thompson, 1998); they are more competent in their interactions with familiar peers and more popular with them (Ladd, 1999; Sroufe, 1983), and they are more social with unfamiliar adults than age-mates with less secure attachment histories, perhaps because of their expertise in exploring the interpersonal environment (Thompson, 1998).

Self-Regulation Theory

10.15.96 I watch as EmaKpendule quietly enters camp with her three children following close behind. The sun is setting and they've been gone since early morning gathering food from the forest floor. This hunger season has been quite severe—taking its toll on the young and old alike. Kpendule, the oldest at age 4, looks around and sees other children helping their mothers, and joins her mother, who is emptying the basket of fruits and nuts. But as she does so she starts to cry—she is hungry and there is little to show for their day's labor. Tears stream down her face, and every so often I hear a muffled sob, yet she continues to help, but now she is placing food on a plate for herself and her sisters. The three of them sit in a circle with the plate of food in the middle. Kpendule picks out just a few morsels and the second oldest does the same; neither says anything as the youngest takes much of what is there. Only a few minutes go by before they finish eating, and when they are done, they stumble into their hut to help their mother prepare their sleeping mats. As they settle down for the night, I hear Kpendule tell her sisters, "We shouldn't cry, tomorrow we won't be hungry. We will go to the water Uala and catch lots of fish."

How children like Kpendule develop culturally appropriate ways of acting and feeling is of interest to researchers studying self-regulation. Examples of self-regulation are evident in the scene just described: Kpendule joining her mother as she empties the basket of food, tak-

ing a small amount of food from the communal bowl, and modulating her distress. Many researchers maintain that the development of self-regulatory processes involves a gradual shift from external to internal mechanisms of control, and they are interested in how this occurs and the consequences of it.

The first signs of children's ability to self-regulate—to act appropriately on their own, by their own choosing, in a flexible and adaptive way—are evident in early childhood (Eisenberg, 2002; Grolnick, McMenamy, & Kurowski, 1999; Kopp, 2001). Early regulatory capacities lay the groundwork for later ones. Infants regulate their states of arousal in the first months of life, and how well they do this relates to their exploration and mastery of the environment at this age. As toddlers, children begin to develop social standards of control and compliance, and as young children they appropriate moral codes of conduct. These emergent regulatory abilities collectively support the young child's developing sense of autonomy—a person with an "independent identity and self-sufficient behavior" (Calkins, Smith, Gill, & Johnson, 1998, p. 351). Contributing to these early accomplishments is the care children receive: "The movement towards autonomy and self-regulation is viewed as rooted in the quality of the earlier infant-caregiver relationship" (Sroufe, 1996, p. 204).

There is no unified literature on self-regulation. Rather, researchers typically examine emotional regulation or behavioral regulation, although some study both, and most acknowledge their interrelatedness (e.g., Calkins, 2004; Eisenberg, 2002; Kochanska, Coy, & Murray, 2001; Stifter, Spinrad, & Braungart-Rieker, 1999). Investigators interested in emotional regulation rely on notions of temperament and, in particular, the constructs of effortful control (temperament that is managed voluntarily) and reactivity (fearfulness, impulsivity) (e.g., Rothbart, 1989; Rothbart & Derryberry, 1981). Investigators interested in behavioral self-regulation draw on self-determination theory. Yet these researchers concur that autonomy is a developmental goal and agree on the type of care that supports its development.

Regulation of Emotional Expressiveness

Theorists concerned with emotional development agree that emotion regulation is goal-

directed and functional in nature (Eisenberg & Morris, 2002).⁴ Emotional regulation is evident early in the life of the child, and it is a central organizing construct, embedded in many other developments (Sroufe, 1979). At first, infants rely mostly on caregivers to manage their affective states (Thompson, 1994), but with time, infants assume more responsibility, and by early childhood, emotion regulation is largely self-initiated. Self-regulation theorists place great emphasis on this shift toward increased autonomy.

The quality of infants' experiences with their caregivers is important to the development of emotional self-regulation. What matters is whether caregivers are sensitive and responsive, rejecting, or act unpredictably in response to infants' emotional signals—especially during times of heightened arousal when infants are feeling threatened. Attachment theorists believe that infants develop a style of emotional expressiveness that best maintains their relationship with close others—a style that develops into strategies for regulating emotions (Cassidy, 1994). When infants are cared for in a sensitive and responsive manner, they learn that it is acceptable for them to express positive and negative emotions, and that seeking help from close others to regulate emotions is an effective strategy. Infants with this attachment history are likely to remain organized in the face of stress, to trust themselves to regulate their emotions, and to be open and flexible in their expression of emotions as they grow up. By comparison, infants with insecure attachment histories are less confident in expressing emotions or they express emotions inappropriately because of the unavailability or unpredictability of their care providers. As children, they are likely to mistrust themselves to regulate their emotion and they respond to stress in rigid or inefficient ways.

There is empirical support for this view. Children with insecure compared to secure attachment histories are more prone to express negative emotions as infants (distress and fearfulness) and are more aggressive as young children (Diener, Mangelsdorf, McHale, & Frosch, 2002; Grossmann et al., 1999; Kochanska, 2001; Weinfield et al., 1999). Moreover, children with insecure attachment histories are more likely to remember negative events, whereas their agemates with secure histories are more likely to remember positive events (Belsky, Spritz, & Crnic, 1996). The expression

of negative emotions, as well as the attention to negative events that is observed in children with insecure attachment histories, point to heightened negative emotionality.

Regulation of Behavior

Behavioral self-regulation rests on the development of accomplishments that occur around the second year of life, such as voluntary control and awareness of standards, along with an ability to evaluate and to adapt one's actions accordingly (Kopp, 2001). One of the more well-studied examples of behavioral self-regulation is compliance to a caregiver's request (Kochanska et al., 2001). Compliance is a heterogeneous construct entailing types that are motivationally distinct: committed and situational compliance (Kochanska et al., 2001). In committed compliance, the child wholeheartedly embraces the caregiver's agenda and endorses it as his own; in situational compliance, the child does not embrace the caregiver's agenda and his compliance is sustained by the caregiver's control.

Eagerly embracing another's agenda, the hallmark of committed compliance, indicates that the child experiences the action as personally endorsed and self-generated (Kochanska et al., 2001). This nascent sense of autonomy is important for the development of internalization and integration (Ryan & Deci, 2000b). By comparison, when a child does not experience a sense of control over the action, as is the case with situational compliance, the action is experienced as an externally controlled regulation, without being processed, coordinated, or endorsed by self (Ryan et al., 1997).

Regulation Strategies

How well children regulate their emotions and behaviors partly depends on their effortful control—the ability to “willfully or voluntarily inhibit, activate, or change (modulate) attention and behavior” (Eisenberg, Smith, Sadovsky, & Spinrad, 2004, p. 260). One measure of effortful control includes indices of attention shifting (or distraction). Infants and young children who use this strategy express less negative emotion (distress, anger; Bridges, Grolnick, & Connell, 1997; Calkins & Johnson, 1998; Grolnick, Bridges, & Connell, 1996; Tronick, 1989) and are able to delay gratification longer (Eisenberg et al., 2004)

than peers using other self-regulatory strategies.

Using a composite measure of effortful control that included an assessment of attentional control, Kochanska, Murray, and Harlan (2000) found that higher effortful control at 22 months predicted better regulation of anger (during frustrating situations) at 22 and 33 months, and joy (during pleasurable situations) at 33 months. Effortful control is also positively related to young children's committed compliance and to aspects of moral development associated with it, and negatively related to externalizing behaviors in early school-age children (Kochanska, 2001; Kochanska et al., 2001; Kochanska, Murray, & Coy, 1997).⁵

Whereas shifting attention is considered one of the more adaptive self-regulation strategies, moving closer to or making contact with an adult, or waiting for a person to intervene, are examples of less adaptive self-regulation strategies, especially for older children. As children get older, there should be a "greater reliance on solitary or intraindividual strategies of regulation/control" (Eisenberg & Morris, 2002, p. 199). These two classes of strategies represent the ends of an autonomy continuum from self-reliant and active to stimulus-bound and passive (Grolnick et al., 1999). A particularly important aspect of autonomous regulation is the ability to use strategies flexibly depending on the context. A child who is able to do this is able to "experience emotions over a range of intensities without the feeling of being out of control" (Bridges & Grolnick, 1995, p. 205).

The type of care that fosters adaptive self-regulatory abilities also fosters healthy attachment relationships.⁶ This care is supportive, warm, sensitive, responsive, nonintrusive (asking if the child needs help, making suggestions, offering explanations), and emotionally positive. In contrast is care that is intrusive, directive (telling the child what to do or physically making the child do something), and emotionally negative (angry, hostile, demeaning). Young children whose mothers are involved with them in positive ways are more likely to rely on adaptive regulation strategies, are less distressed in situations meant to elicit negative emotions, show more committed compliance, and score higher on measures of conscience than are children with mothers who are less positive and supportive of them (e.g., Calkins & Johnson, 1998; Feldman, Greenbaum, & Yirmiya, 1999; Kochanska & Murray, 2000; Silverman & Ippolito, 1995).

Scholars provide many reasons why positive care fosters adaptive regulatory abilities and the competencies associated with them, but what is basic to all is the view that this type of parenting is a minimal threat to the child's autonomy and in fact supports its development. Often cited is the explanation that sensitive care provides children with varied opportunities to observe and practice valued ways of regulating emotions and behavior on their own, with a sense of self-discovery and self-confidence. By contrast, care that thwarts children's autonomous functioning deprives them of the feeling that they have a say in things—a sense of choice and control that comes when children are able to mobilize resources they want (when others respond to their bids and follow their lead). What contributes to these feelings of choice and control is parents who are willing to negotiate or share power with their child (Crockenberg & Litman, 1990).

Our discussion of healthy attachment relationships and adaptive self-regulation says a lot about valued ways of being a person in middle-class U.S. and Western European communities. Attachment relationships and self-regulation are conceptualized in ways that make sense given the values of the people most often studied and of the researchers who most often study them. However, other ways of being a person in the world reflect ethics besides autonomy, such as ethics of community (duty, hierarchy) and divinity (sacred order, natural order) (Shweder, Much, Mahapatra, & Park, 1997), and this raises questions about the appropriateness of Western-based notions of healthy development for people who live by these ethics. We now consider the self more broadly than how it is portrayed by the theories and research we reviewed earlier, examining "the way culture, community, and psyche become coordinated and make each other possible" (Shweder et al., 2000, p. 868). We then consider attachment relationships and self-regulation from this perspective.

MULTIPLE SELFWAYS— MULTIPLE DEVELOPMENTAL PATHWAYS

The *self* determines what a person notices, thinks about, feels, and remembers; how and why a person relates to others; what it means to be an acceptable, good, and moral person; and how a person organizes, interprets, and makes sense of experiences. This means that

the experience and expression of self is integral to psychological processes such as attachment and self-regulation. The self develops as infants and children take part in the day-to-day life of their community—in culturally organized practices, routines, and traditions that provide opportunities to develop valued ways of being a person in the world (Rogoff, 1990). Cultural practices and contexts are one side of a “two-sided thing” (Shweder et al., 2000, p. 874), the other side is the mentalities associated with them. Mentalities are what we know, want, feel, value, and believe. They give form and meaning to practices and are reflected in them.

An Efe example illustrates how practices and mentalities relate, and how community members foster the development of similarly minded infants and children. As soon as infants are able to toddle, around 8 or 9 months of age, they are asked to carry bits of food and other delectable items to different camp members. When the infant places the item in the person’s hand, the person immediately places it back in the infant’s hand and asks the infant to return it to the person who sent it, or to give it to someone else. It is not unusual for this to go on for awhile and everyone seems to enjoy it. Infants are engaged in this “game” until they are about a year old. When asked about this routine, camp members say that it is important for children to learn when they are young the value and practice of sharing, particularly when this means giving away desirable items to the people with whom they live. Sharing is critical to the survival of the Efe: People must depend on each other for many things, especially food, because the success of a hunt or a gathering expedition is never guaranteed. But sharing is more than this: It connects people to one another, making public, confirming, and authenticating social relationships; it is a way to express affection, friendship, and good will.

Ways of being a person in the world are culturally and historically grounded and at the same time personal: *personal* because of the peculiarities of an individual’s experiences; *cultural* because people of a community participate in a system of practices and beliefs that foster a shared understanding of valued ways of acting, feeling, and thinking; and *historical* because cultural practices and beliefs are “passed down” from one generation to the next. Generational transmission is not a passive process. Individuals reproduce, as well as produce, aspects of culture, which is as dynamic as the people who constitute and are

constituted by them. Markus, Mullally, and Kitayama (1997) refer to “self” and “selfway” to distinguish between the personal and cultural–historical aspects of self (although this distinction does not imply that these aspects of self are divisible). Selfway is a characteristic way of being a person in the world that develops because of the culturally mediated experiences people of a community have in common. Self is the personalization of this characteristic way.

The relation between self and selfway is nicely illustrated in a conversation one of us had with a U.S. middle-class mother of European descent who was asked to tell us where her young infant slept and why (Morelli, Rogoff, Oppenheimer, & Goldsmith, 1992). She hesitated at first, then told me that her 1-year-old son sleeps with herself and her husband. She laughed awkwardly and quickly added that no one knew this, especially her mother, who would have been very upset had she known. This mother decided not to participate in a practice common to people like herself and promoted by experts in the field. Still, she was aware of what was expected of her, and her resistance to the practice of sleeping in a bed (and even a room) separate from her infant was a source of concern.

Cultural Patterning of Selfways and Self

Two well-researched selfways, independence and interdependence, were once considered to be opposites. The former emphasizes autonomy (internal control, individual choice, personal agency) and the latter, heteronomy (conformity, obligation, reciprocity, and loyalty).⁷ However, for all of us, agency, choice, loyalty, and obligation are important in certain situations at certain times in our lives. As researchers acknowledged this, it began to make less sense to think of selfways in dichotomous ways. The revision in thinking, and the research that led to it, suggests that individuals develop heterogeneous orientations—with different emphases on independent and interdependent orientations in different contexts (e.g., Shweder et al., 2000). But how these qualities are experienced and expressed by people relate to the culture’s predominant value system: “Although independence and interdependence are viewed as dimensions of functioning in any culture, they are expected to take on different meanings when they are part of different cultural value systems” (Raeff, 1997, pp. 212–

213; see also Markus et al., 1997; Shweder et al., 2000).

Autonomy is the ethic that underlies the independent selfway and North Americans' and Western Europeans' views of the self. What these people notice, how they make sense of it, and what they do as a result are likely to rest more on their perceived personal qualities, such as traits, attributes, and talents, than on situational or relational qualities. These personal qualities are the defining feature of self for this selfway and are the source of self-knowledge (Suh, 2000). Reference to and affirmation of these qualities, which promote a tendency toward self-expression and self-enhancement are likely to support the self-determining attitude required for being a valued person (Shweder et al., 2000).

People living elsewhere rely on different ethics to justify their way of being. The ethics of community prevalent in many East Asian societies places great value on virtues such as respect, duty, and obligation, privileges situational and interpersonal qualities, and underlies the interdependent selfway. What is important to this self is the self-in-context, especially the interpersonal context. For example, Miller (1984) observed that older Indian children relied more on contextual factors to explain social situations, whereas older children in the United States relied more on individual, stable, personality traits. Ip and Bond (1995) found that Chinese participants referred more often to social roles when describing themselves than did North American participants. And Japanese students were twice as likely as European American students to include other people in their self-descriptions (50% compared to 24%) (Markus et al., 1997). People in communities with this ethic prioritize harmonious connections, which require knowing and meeting the expectations of others (Weisz, Rothbaum, & Blackburn, 1984a). Expressions of self-criticism and the need for self-improvement make possible this moral good, as do acts to fit in socially (Weisz, Rothbaum, & Blackburn, 1984b). Self-expansive actions, of which expressions of happiness are an example (Kitayama, Karasawa, & Mesquita, 2004), and acts that call attention to self or emphasize the distinct and uniqueness of self, threaten harmony.

The ethics by which people live relate not only to how competencies are defined but also to how they develop. Keller and colleagues pos-

tulated that competencies such as healthy attachment and adaptive self-regulation develop along one of two developmental pathways (Greenfield, Keller, Fuligni, & Maynard, 2003; Keller, 2003). They proposed a component model of parenting made up of different parenting systems, including body contact, body stimulation, object stimulation, and face-to-face exchange. The way practices relate within and across systems suggest two parenting styles. The proximal style emphasizes bodily closeness, and the distal style emphasizes physical separateness and distance. These styles are related respectively to the development of an interdependent and independent selfway (Keller, Lohaus, Volker, Cappenberg, & Chasiotis, 2004; Rothbaum & Trommsdorff, 2006). Another formulation of developmental pathways is provided by Rothbaum, Pott, Azuma, Miyake, and Weisz (2000), who suggest that close relationships in Japan are characterized by efforts to achieve "symbiotic harmony," and that relationships in the United States are characterized by efforts to achieve "generative tension." Rather than depicting these cultures as differing in their investment in relationships, they review evidence suggesting that they differ in the meaning and dynamics of relationships.

We now consider young children's attachment relationships and self-regulation growing up in societies where ethics like community are important. In doing so, we revisit the thesis that healthy development inevitably involves internalization and integration (internal cohesion) that are critical to autonomous functioning. We proceed cautiously, however, because the cultures we refer to as living by ethics of community differ in how this ethic is experienced and expressed in everyday life, as do cultures living by ethics of autonomy.

BROADENING OUR THINKING ABOUT ATTACHMENT RELATIONSHIPS

We begin by asking whether our understanding of attachment relationships changes when we include in our theories people whose way of being a person are rooted in ethics of community or divinity—where what they notice, feel, think about, and remember are motivated by situational and interpersonal considerations more often than not. We accept the challenge implied by LeVine and Norman (2001) when they said,

“The study of attachment . . . gave rise to an approach as blind to culture as any other in psychology” (p. 86). Below, we reexamine central tenets of attachment theory, this time considering research in communities where autonomy is not as central a concern.

Our thesis goes beyond suggesting that culturally informed research just consider the possibility that the circumstances of a child’s life, including cultural circumstances, relate only to the quality of the attachment relationship. Rather, it must also consider the very premises underlying traditional attachment theory. We posit that the very essence—the very meaning—of attachment relationships is related to ethics by which people live. Among people living by ethics of community, attachment relationships are based more on goals involving interdependence—harmony, duty, and obligation. Accordingly, the attachment system is more undermined by inability to depend on and fit in with others than on inability to gain autonomy. The care experiences that foster this type of attachment relationship and related competence are also fundamentally different (Rothbaum, Weisz, Pott, Miyake, & Morelli, 2000).

The Secure Base from Which to Explore and Security of Attachment Relationships

At the heart of the notion of attachment security is the concept of a secure base. “For both Bowlby and Ainsworth, to be attached is to use someone preferentially as a secure base from which to explore” (Waters & Cummings, 2000, p. 165). We maintain that attachment theorists’ conceptualization of the secure base reflects the Western emphasis on exploration and the belief that exploration leads to an independent selfway. As noted by Seifer and Schiller (1995), “Secure base behavior provides a context in which differentiation of self and other can take place” (p. 149). Japanese attachment experts are less likely to emphasize a dynamic that is so centered on individuation. According to Takahashi (1990, p. 29), “Mothers’ effectiveness in serving a secure base function well represents the quality of attachment only in the American culture, in which social independence or self-reliance is emphasized.”

Few studies have adopted emic or derived etic methods (culturally sensitive measures) when examining the nature of security in non-Western (“majority world”) cultures.⁸ To our

knowledge, only Harwood, Miller, and Irizarry (1995) have used open-ended methods to explore indigenous concepts pertaining to the nature of the secure base. These investigators focused on the key attachment theory concept of optimal balance (alternating between exploration/autonomy and attachment/relatedness). They found that “Puerto Rican mothers conceptualized optimal balance in terms of . . . a contextually appropriate balancing of calm, respectful attentiveness with positive engagement in interpersonal relationships [rather than] . . . in terms of autonomy and relatedness” (p. 112). As expected, the balance of autonomy and relatedness was the primary theme emerging from the interviews with the Anglo mothers.

In summarizing their findings, Harwood and colleagues (1995) comment: “The construct of security versus insecurity has become equated in U.S. psychology with a host of culturally valued qualities that are specific to the socialization goals of our highly individualistic society, thus limiting their cross cultural meaningfulness” (p. 114). This captures well our concerns about current conceptualizations of security—that they are grounded in independent ways of being and the emphasis on autonomy. In Puerto Rico, people live by ethics of community and are relatively more concerned with respect, duty, and obligation. For them, attachment has more to do with awareness of persons and situations in which these values must be exhibited.

Observations of infants in different cultures suggest that there may be a biological basis to the link between attachment and exploration (Van IJzendoorn & Sagi, 1999). However, the extent to which exploration occurs, and the primacy of the link between attachment and exploration, varies across cultures. Japanese babies have repeatedly been observed to engage in less exploratory activity than U.S. babies, including in the Strange Situation (reviewed in Rothbaum, Weiss, Pott, Miyake, & Morelli, 2000). Moreover, whereas Japanese babies are more oriented to their mothers in circumstances involving both distress and positive emotions, U.S. infants are more oriented to the environment in such circumstances (Bornstein, Azuma, Tamis-LeMonda, & Ogino, 1990; Friedlmeier & Trommsdorff, 1999).

Whereas the link between attachment and exploration behavioral systems is seen as primary in many middle-class U.S. and Western

European communities, the link between the attachment and dependence behavioral systems appears primary in majority world communities, including Japan and Puerto Rico. Just as exploration during infancy fosters ethics of autonomy, dependence fosters ethics of community. In Japan there is a greater emphasis on accommodation or "social fittedness" (Emde, 1992) and related qualities including empathy with others, compliance with their wishes, and responsiveness to social cues and norms. Support for our view of attachment in the life of Japanese children comes from the study of *amae*, an indigenous Japanese concept that refers to relationships involving both attachment and dependence (Doi, 1989; Emde, 1992; Okonogi, 1992). According to Doi (1992) *amae* means "to depend and presume upon another's love or bask in another's indulgence" (p. 8); *amae* is "what an infant feels when seeking his or her mother." The parallels between *amae* and attachment in their developmental course, antecedents, consequences, and role in adaptation (Emde, 1992; Okonogi, 1992; Rothbaum, Kakinuma, Nagaoka, & Azuma, 2005), led Doi to conclude: "The concept of attachment which was introduced by John Bowlby . . . obviously covers the same area as *amae*" (1989, p. 350).

The view that *amae* is an attachment-related construct for relationships in Japan is supported by research that uses a modified separation-reunion paradigm with preschool children (Mizuta, Zahn-Waxler, Cole, & Hiruma, 1996). Mothers and their children were observed during preseparation and reunion episodes for attachment (e.g., proximity, anxiety, and avoidance) and *amae*-related behaviors (e.g., dependence). The emotion language mothers and children used when talking about past separations and reunions was noted as well. The researchers observed that compared to U.S. children, Japanese children exhibited more dependent behavior characteristic of *amae* when reunited with their mothers; following the reunion, Japanese mothers and their children expressed more feelings of sadness due to separation (presumably related to interpersonal loss) and less feelings of fear (presumably related to perceived danger) than their U.S. counterparts. Mizuta and colleagues speculated that, for the Japanese children, attachment has more to do with meeting *amae* needs (for indulgence and interdependence) than meeting needs for autonomy and exploration.

Whereas separation activates the attachment system in both cultures, activation is associated with threats to very different needs. Japanese children's *amae* behaviors on reunion signaled their perception that their needs for indulgence and interdependence were threatened, and Japanese mothers responded to them by engaging their *amae*-related behaviors (providing proximal reassurances), presumably to reaffirm the relationship. *Amae*, the authors conclude, "may be an appropriate means of deactivating an attachment system aroused by interpersonal loss more than exploratory risk" (p. 156). Findings with adults also indicate a closer link between attachment and *amae* in Japan than in the United States (Kondo-Ikemura & Matsuoka, 1999).

These cultural differences in views regarding children's relationships may relate to the higher levels of "insecure-ambivalent" babies and lower levels of "insecure-avoidant" babies in Japan than in the United States (Van IJzendoorn & Sagi, 1999). There are many similarities between descriptions of insecure-ambivalent behaviors and behaviors widely regarded as adaptive in Japan, including exaggerated cute and babyish behaviors (Main & Cassidy, 1988), extreme expressions of need for care and attention, extensive clinging and proximity seeking, helpless dependency (Cassidy & Berlin, 1994), extreme passivity, blurring of boundaries between self and other (Weinfield et al., 1999), and failure to engage in exploration (Ainsworth et al., 1978). Many of these features of ambivalent behavior characterize the normal *amae* relationship in Japan (Doi, 1973; Kondo-Ikemura & Matsuoka, 1999; Lebra, 1994; Mizuta et al., 1996).

Sensitive Care and Security of Attachment Relationships?

Carlson and Harwood (2003) found that, as predicted, mothers' physical control related to insecure attachment in Anglo American families, but not in Puerto Rican families: "The highest ratings of physical control were associated with secure 12-month attachment status for these middle-class Puerto Rican dyads. This apparently paradoxical finding highlights the need for culturally specific definitions of sensitive caregiving" (p. 17). These findings stand in stark contrast to Western findings, reviewed earlier, that responsive, nonintrusive, autonomy-fostering maternal practices hold

the key to secure attachment. According to Carlson and Harwood, physical control is part of a larger system of practices and beliefs among Puerto Rican mothers. “Teaching infants to be attentive, calm, and well behaved requires considerably more physical prompting and control than teaching infants to be assertive and self-confident. Thus it appears that maternal use of physical control may be regulated by maternal socialization goals” (p. 18).

Interestingly, parental control, directiveness, and strictness are more valued and emphasized in many cultural and ethnic communities—African American, Korean, Chinese, and Iranian—than they are among European Americans (Carlson & Harwood, 2003). Members of all of these groups subscribe to a selfway that emphasizes the importance of accommodating oneself to the needs of others and to situational demands, and seeking harmony with others. Children who have experienced controlling caregiving are more likely to find security in relationships characterized by clearly prescribed role expectations, where their own and their partner’s accommodation will cement close ties. Future research may show an association between parental control and security in all of these cultural groups. By contrast, Western attachment theorists maintain that efforts to physically control, shape, or interfere with infants’ activity are associated with insensitivity and insecurity. The link between autonomy fostering and security—which is assumed to be universal by attachment theorists (Allen & Land, 1999; Belsky, Rosenberger, & Crnic, 1995)—may be a predominantly Western phenomenon (cf. Dennis, Cole, Zahn-Waxler, & Mizuta, 2002).

Cultural studies suggest as well that the timing of caregivers’ response to babies’ signals may not be the same across cultures. Western investigators evaluate caregiver’s behavior in terms of its responsiveness—how contingent the response is (immediately after) to the child’s overt signal. By contrast, studies in other cultures emphasize the ways caregivers anticipate shifts in a baby’s emotional state and respond proactively (or respond to very subtle and covert signals). Anticipatory responsiveness is reported among the Japanese (Rothbaum, Nagoaka, & Ponte, 2005; Trommsdorff & Friedlmeier, 2003), the Nso of Cameroon (Voelker, Yovsi, & Keller, 1998), and Puerto Ricans and Central American immigrants in the United States (Harwood, 1992). Under-

lying U.S. caregivers’ reliance on responsiveness is their emphasis on children’s autonomy, children’s responsibility for clarifying their needs, and the value of children’s explicit signals. Underlying Japanese caregivers’ reliance on anticipation is their emphasis on children’s dependence on others, caregivers’ responsibility for clarifying children’s needs, and the value of caregivers’ assumptions about children’s needs (Rothbaum et al., 2005).

Cultural differences in proactive compared to reactive responses to babies’ signals may reflect prioritization of selfways emphasizing harmony and context-embeddedness versus autonomy and individuation (Keller et al., 2003). Proactive caregiving may pave the way for attachment relationships that emphasize interdependence, extreme empathy, merger of self and other, and heightened attentiveness and sensitivity to situational demands.

Competence and Attachment Relationships?

Just as there are differences in the nature of security and practices fostering it, there are differences in competencies that follow from security. Attachment theorists emphasize Western values and behaviors associated with autonomy, including exploration, self-assertion, self-esteem, and independence. By contrast, “from [an East Asian] perspective, an assertive, autonomous . . . person is immature and uncultivated” (Fiske, Kitayama, Markus, & Nisbett, 1998, p. 923).

Other investigators also highlight cultural differences in conceptions of competence. Keller (2003) notes that Western-based ideas of competence—which emphasize individual ability, cultivation of the individual mind, exploration, discovery, and personal achievement—are fundamentally different from conceptions seen in many other societies, such as the Baoule of the Ivory Coast, A-Chew of Zambia, Nso of Cameroon, Cree of Alaska, Hindu of India, and Chinese of mainland China and Taiwan. In these majority world societies, competence is considered “as moral self-cultivation, a social contribution, discouraging individual celebration of achievement . . . [and] as communal achievements, including the ability to maintain social harmony implying social respect and acceptance of social roles” (p. 289).

Other cultural studies support Keller’s view. In their conversations with mothers, Harwood et al. (1995) found that Anglo mothers’ views

of social competence centered on self-maximization and independence, as seen in their emphasis on autonomy, happiness, confidence, and exploration. For Puerto Rican mothers, social competence involved “proper demeanor” and interdependence, as seen in their emphasis on respect, obedience, calmness, politeness, gentleness, and kindness. “Proper demeanor” refers to more than appropriate ways of relating to others; it also refers to what is described in English as “teachable.” It involves a receptivity to one’s elders “in order to become skilled in the interpersonal and rhetorical competencies that will someday be expected of the well-socialized adult” (p. 98). If attachment research had its origins in non-Western cultures, we suspect that qualities such as proper demeanor (and *sunao*—a similar Japanese construct) would be considered universal consequences of security.

BROADENING OUR THINKING ABOUT SELF-REGULATION

Eisenberg and Zhou (2000) raise the possibility that “people in individualistic and collective cultures differ in their standards for emotion regulation, beliefs and values regarding an optimal state, or attention to and perception of their own emotional state” (p. 169). We elaborate on this observation, examining self-regulation mostly in African and East and Southeast Asian communities. For these people, the *self* in *self*-regulation is less concerned with internal attributes and qualities and more concerned with situational circumstances. Adaptive self-regulation in these communities, like healthy, close relationships, more often includes efforts to achieve relational harmony than personal autonomy. Regulatory processes reflect a heightened concern with interpersonal contexts (self-presentation to gain acceptance) compared to personal contexts (delay of gratification when alone). Because of this, they are likely to differ in form, function, meaning, and circumstances of occurrence.

Self-Regulation of Emotions and Behavior

When people live by ethics of autonomy, emotional expressiveness⁹ often draws attention to their inner qualities and attributes. These emotions cover the gamut from positive to negative, including frustration and anger. Positive emotions are perhaps the most desirable be-

cause they foster and protect personal esteem, which sustains the autonomous self (Mesquita, 2003). This is not like the emotional expression of people for whom community is paramount. For them, socially engaging emotions that bind people together (e.g., empathy and shame) are valued. Positive emotions are valued by people who live by ethics of community when they foster and strengthen social ties, as seen in many Asian societies, for example (Kitayama, Markus, & Kurokawa, 2000). Ego-based, socially disengaging emotions that disrupt harmony, such as anger, frustration, and pride, are seen negatively (Kitayama et al., 2004; Markus & Kitayama, 1991). These people have a heightened awareness of their audience’s expectations, and regulatory processes are attuned to situational cues and reflect more consideration of social norms than of personal attitudes and beliefs (Kitayama & Markus, 1999). Adaptive self-regulation leads to responsive coordination with others and, ultimately, relational harmony.

There is evidence to support this view. Japanese students and community members were asked what they would do if offended by another person. Common answers included doing nothing, taking responsibility for the offense, and seeking closeness to the offender, all of which reflect concerns about relational harmony and efforts to repair the relationship. By comparison, American students were more likely to blame the offender (69%)—a disengaging response (Mesquita, Karasawa, Haire, & Izumi, 2002, cited in Kitayama et al., 2004). Japanese students also said that they experience more interpersonally engaged emotions in everyday social situations and generally felt more positive when they did; the valence of the emotion (whether shame or empathy) mattered less to them. By comparison, North American students preferred positive emotions—emotional valence was key—and were generally more positive when experiencing interpersonally disengaged emotions (those reflecting independence).

Even at young ages, children’s experience and expression of emotions are consistent with the ethics of the society in which they live. Among Indonesians, the expression of negative emotions is infrequent, but when they are expressed, young children’s healthy functioning is compromised. Third-grade Indonesian children are likely to respond to family members’ relatively nonhostile, low-key negative emotions with poorer performance on measures of self-

regulation (attentional control and inhibitory control), sympathy, and externalizing behaviors, according to their parents. Family members' expression of positive emotions, however, was not related to children's enhanced functioning, unlike what is often observed in the United States (Eisenberg, Liew, & Pidada, 2001). Compared to North American preschoolers, Japanese preschoolers responded to hypothetical emotionally challenging situations (involving interpersonal conflict and distress) with fewer references to anger and aggression, highlighting Japanese children's desire not to harm others (Zahn-Waxler, Friedman, Cole, Mizuta, & Hiruma, 1996). When asked what they would do in the situation, North American, but not Japanese, preschoolers said they would avoid the person involved—a disengaging strategy.

Emotional regulation sometimes takes place at the level of appraisal (what a person notices and attends to), minimizing expressions of disruptive emotions. We see this among the Utku Inuits (Briggs, 1970), Tahitians (Levy, 1973), and Nepali Tamang (Cole & Tamang, 1998). Six- to 9-year-old Tamang children participating in a study similar to the one by Zahn-Waxler and colleagues (1996) just described reported feeling "okay" when asked about these emotionally challenging situations. Their responses suggested that the situations were not appraised as emotionally significant to them, which is consistent with the peaceful and calm demeanor valued by the Tamang. By contrast, for the Chhetri-Brahmin children participating in this study, regulation took place at the level of expression. Although these children consistently reported feelings of anger in these situations, they said that they would mask their emotion so others would not know about them (show no facial signs of the felt emotion).

Children living in other East Asian and Southeast Asian communities such as Korea, China, and Thailand, are often described as overregulated in their emotional expressions compared to their North American agemates. Chen and her colleagues (1998) found that Chinese 2-year-olds scored higher on measures of behavioral inhibition in their reaction to a scary object in a laboratory situation than did Canadian toddlers. Almost half of the Chinese children did not even touch the object (47%), whereas most Canadian toddlers did (88%). The shyer (behaviorally inhibited) the Chinese child, the more likely was his mother to express warm and accepting attitudes toward him,

which was untrue of Canadian mothers of shy children.

Historically, shyness among the Chinese was considered mature and sensitive, unlike expressiveness, which was regarded as nonadaptive and immature regulation (Ho, 1986). Shy children fared well in terms of peer acceptance, leadership, and academic achievement (Chen, Cen, Li, & He, 2005; Chen et al., 2003). By contrast, shy North American children do not fare well; they are more prone to internalizing problems such as social withdrawal and depression (Eisenberg, 2002), are regarded as socially inept or immature, and have poor peer relations (Eisenberg & Zhou, 2000). However, today in China, the shy child is doing less well. Chen et al. (2005) examined measures of elementary school-age children's social and academic functioning, including shyness, at three different points in time—1990, 1998, and 2002. Whereas shyness in the 1990 cohort was associated with positive outcomes like those just noted, in the 2002 cohort it was not. Rather, shyness was correlated with peer rejection, school problems, and depression. Shyness, once traditionally valued and encouraged, is now seen as an impediment to developing qualities, such as social assertion and initiative, that many consider necessary for success in China's increasingly capitalistic system.

The emotion of feeling-with-others, or empathy, is important for connecting people with one another (Saarni, 1997); in fact, it may be considered the quintessential interpersonally engaging emotion. Empathetic-related responses take into account, and accommodate to, the needs of the other in appropriate, prosocial ways (Roberts & Strayer, 1996). In Japan, empathy helps a person "avoid inconveniencing, annoying, or imposing on others" (Clancy, 1986, pp. 233–234). Japanese mothers consider empathy, as well as obedience and good manners, a self-regulatory function that increases with the age of the child (Rothbaum, Kakinuma, et al., 2005; Kashiwagi, 1988, cited in Ujiie, 1997).

Placing the burden of understanding people's needs and intentions on the listener may support the development of empathy and, more broadly, the sensitivity and responsiveness to others that are important to the regulatory processes maintaining relational harmony. A good listener must notice and attend to the speaker and other relevant situational cues to intuit what another has on his or her mind. Japanese mothers help children learn this competency by

telling them directly what others are thinking and feeling in various situations (Clancy, 1986). Similarly, among the Kaluli of New Guinea, mothers speak for their babies, teaching them what to say in social situations (Ochs & Schieffelin, 1984).

In many U.S. middle-class families, by comparison, the speaker rather than the listener is responsible for effective communication. The speaker must make himself heard and understood—regulating the volume, animation, and persistence of the messages to make it clear what he is trying to say. An example of U.S. children's responsibilities as speakers is observed in a study where European American middle-class mothers and Efe mothers were asked to show their child how to work a difficult toy, then asked to shift their attention from their child to the researcher to answer some questions (Morelli, Verhoef, & Anderson, 1996). Representative of the U.S. children was Sara, who marched back and forth, breaking the line of vision between her mother and the researcher, chanting "Look at me, look at me." Finally Sara grabbed her mother's face in her hands, turned it toward her face and yelled, "Look at me!" This child was responsible for regulating her expressiveness to communicate her needs and did so using overt actions and distal verbal strategies. The Efe children depend more on relatively subtle behaviors, such as increased proximity, gentle touch, and postural shifts that relied on their mothers to make sense of their needs, and that did not disrupt the flow of adult activity (see also Rogoff, Mistry, Goncu, & Mosier, 1993).

Empathetic expressiveness is an important element of social relations for people everywhere. Two-year-old German and Japanese girls expressed comparable levels of empathy (when one's own emotional reaction is congruent with the emotional reaction of the other) in a situation designed to elicit this emotion—when a playmate (stranger) expressed sadness over a broken toy (Trommsdorff, 1995). However, compared to the German girls, the Japanese girls were more distressed (upset, anxious, uneasy) by their playmate's sadness and were less likely to recover from it (stayed tense) even though their mothers were as likely to respond contingently to their distress (Friedlmeier & Trommsdorff, 1999). By Western standards the distress reaction of the Japanese girls would represent difficulty in adaptively regulating empathy, leading to overarousal, which is considered aversive and is thought to promote a con-

cern about one's self at the expense of a concern for others (Eisenberg, Smith, et al., 2004). This was true for the German girls; for the Japanese girls, feelings of empathy-related distress did not interfere with their ability to act in a prosocial manner toward the playmate (Trommsdorff & Kornadt, 2003). In other contexts, distress may cause Japanese children to focus on themselves, but distress in empathetic contexts seems to be associated with increased concern for others.

In this study, the Japanese girls were more likely to regulate their distress by seeking physical closeness with their mothers than were the German girls, who were more likely to use eye contact. Unlike the German girls, the Japanese girls did not approach the playmate; they remained close to their mothers, leaving it up to the playmate to approach them. Similarly, young Chinese children stayed closer to their mothers in novel situations meant to elicit stress than did Canadian children (Chen et al., 1998). Physical proximity as a regulation strategy is considered immature by Westerners; however, it is more compatible with people concerned with relational harmony, and it is consistent with many other aspects of care—such as co-sleeping, co-bathing, and prolonged periods of holding—that maximize proximity. Heightened proximity is likely accompanied by lower levels of autonomy (Rothbaum & Trommsdorff, 2006). Distal forms of closeness such as eye-to-eye contact by comparison are more compatible with autonomous self-regulation, which in the West is a hallmark of maturity.

Fitting in, rather than standing out, is important as well to relational harmony (Rothbaum, Weisz, & Snyder, 1982). The practice of self-criticism is one way to achieve fit. Self-criticism shows that a person is aware of her shortcomings and is willing to improve on them (Mesquita, 2003; Shweder et al., 2000). This involves sensitivity to the expectations of others and to the demands of the situation (e.g., see Chao, 1992). We see signs of self-criticism in East Asian children starting at an early age. Stigler, Smith, and Mao (1985) found that Chinese elementary school students rated their competence in the cognitive, physical, and general domains lower than did their North American age-mates. In school, Japanese children are given time to reflect on what was not done to meet idealized standards and to consider ways to improve in the future (Heine, Markus, Lehman, & Kitayama, 1999). Among the Chinese, mothers speak of themselves as more re-

jecting and less accepting of their children than do Canadian mothers (Chen et al., 1998), and they use storytelling to talk about their children's transgressions in ways that are highly critical of the child (P. J. Miller, Fung, & Mintz, 1996). Similarly, Korean parents make clear that their children do not fulfill their hopes (Markus et al., 1997).

Self-discipline in the form of perseverance and endurance makes it possible for East Asian children to strive to meet the expectations of others. The Koreans have a term—*sugohaseyo*—that captures this ethos: “No matter hard you work, you can always work harder” (Grant & Dweck, 2001, p. 207). Tobin, Wu, and Davidson (1989) describe a scene in which Chinese preschoolers, working silently for 20 minutes, build, tear down piece by piece, and rebuild structures exactly as they appear in a picture. This attention to order and regimentation is seen as an important part of children's learning self-regulation, discipline, and social harmony. But one U.S. preschool teacher remarked, upon viewing a videotape of these children, “I guess what bothers me most is that there is such an overemphasis on order and on behaving properly at the cost of stamping out the children's creativity . . . instead of [allowing them] to play in a natural, imaginative way” (p. 92). In the West, this type of persistence would probably not be characterized as adaptive self-regulation, because it does not appear to be autonomous and flexible.

Because of their emphasis on self-improvement, many East Asians attribute their achievements to effort rather than ability. For example, fifth-grade Korean children were more likely to say that they would work harder if they experienced an academic setback than were their North American age mates (Grant & Dweck, 2001). This is consistent with the Japanese notion of “becoming better” (Heine et al., 1999, p. 771). When a person's efforts are not enough to meet the expectations of others, he is likely to experience great distress—high self-blame and negative affect—in part because he is acutely aware of and sensitive to other's opinion of him, and his failures reflect poorly on close others. Unlike Western standards, this distress would not be seen as a failure to self-regulate adaptively, because it motivates children to persevere in their attempts toward self-improvement (Chang, 2001).

East Asian and African adults' encouragement of compliance further indicates that they link self-regulation with relational harmony. Japanese mothers cajole their children into

complying by relying on appeals to empathy (how they are hurt by the situation), social disapproval, and withdrawal of attention by ignoring the child. Clancy (1986) describes a Japanese mother coaxing a child to do what she was told by offering to help the child, doing it along with the child, or watching as the child performed the assigned task. U.S. parents, in comparison, use ego-enhancing strategies such as praise, encouragement, and reference to the child's accomplishments to motivate children to do what they are told (see review by Abe & Izard, 1999; see also Dennis et al., 2002).

Japanese adults tend not to view children's resistance to requests as establishing personal boundaries or seeking autonomy, but rather as selfishness and egocentrism (Yamada, 2004) or as a sign of the child's immaturity: “He is only a child, he'll have time to brush his teeth when he is older” (Osterweil & Nagano, 1991, p. 369). This does not mean that Japanese parents are less tolerant of children's resistance; rather, they attribute it less to needs for autonomy and more to needs for maturity (Lebra, 1994). In several African communities, non-compliance is considered a moral transgression (Nsamenang, 1992). In middle-class U.S. communities, however, noncompliance is sometimes considered a sign that the child is acting autonomously. Older children are seen as showing more mature forms of noncompliance such as bargaining and negotiation, and mothers' responses to their children's non-compliance changes accordingly (Kuczynski, Kochanska, Radke-Yarrow, & Girmius-Brown, 1987). Mothers of children using these more mature noncompliance strategies are more likely to countermand by reasoning and counter negotiation. Ujiie (1997) notes that U.S. parents' encouragement of the child not to comply with seemingly unfair requests—which he calls assertive autonomy—is difficult for many Japanese to understand or accept, because this goes against the virtue of adjusting one's needs to the needs of the group. Ujiie notes that Japanese comments such as “He is assertive” or “He has a self” are typically pejorative.

Developmental Pathway to Interdependent Self-Regulation

Keller, Yovsi, et al. (2004) explored the premise that East Asian and African children's early care experiences underlie the development of self-regulatory processes that reflect heightened

concerns with relational harmony. They examined the maternal correlates of infants' and toddlers' self-regulation in communities differing in their emphasis on autonomy and community—the Nso of Cameroon (representative of an interdependent cultural pathway) and Greek infants of Greece (representative of an independent cultural pathway). They identified two styles of parenting associated with these different ethics (Keller, Lohaus, et al., 1999) and argued that the distal style, with its emphasis on face-to-face contact and object play, was more likely to foster in children a concern with issues of personal autonomy and separateness; the proximal style, with its emphasis on bodily closeness, in contrast, was more likely to foster in children a concern with issues of heteronomy and relatedness.

Keller, Yovsi, et al. (2004) reasoned as well that the timing of accomplishments such as self-regulation (e.g., committed compliance) and self-recognition would depend in part on the importance of the ethics by which people lived. Compliance is extremely important among many East Asians and Africans; the press for early compliance is noted in the Gusii of Kenya (LeVine, 2004), the Efe of the Democratic Republic of Congo (Morelli, 1997), among children living in Nyansongo in Kenya, and among the Chinese (Chao & Tseng, 2002; Chen et al., 2003). Similarly, Japanese babies are pressed to develop indirect speech forms, assumedly to help fit in and not offend (Clancy, 1986). For example, the Japanese language allows a speaker to negate entire sentences once spoken to make an assertion less direct, perhaps in response to the listener's expression. Japanese people rarely disagree or say "no" in public to avoid offending another or others. Self-recognition, by contrast, is consistent with a child's sense of self as separate and autonomous, and the early press for self-recognition is more often seen among Western parents.

Keller, Yovsi, et al. (2004) found that, within culture, the proximal parenting style relates to the development of self-regulation and the distal parenting style, to the development of self-recognition. Between-culture differences were also found: The Nso infants, who experience greater proximal contact, develop self-regulation earlier than do Greek babies, and Greek babies, who experience greater distal contact, develop self-recognition earlier than do Nso infants; that is, the caregiving practices that predict later self-recognition and self-regulation are similar across cultures, but the

emphasis on these caregiving practices and the emergence of the developmental outcomes with which they are linked differ. Keller, Yovsi, et al. relate the cultural differences in caregiving and in their developmental outcomes to differences between the communities in their prevailing ethics, namely, the Nso emphasis on interdependence (i.e., concerns with community) and the Greek emphasis on independence (i.e., concerns with autonomy).

Broadening Our Conceptions of Good Care

The proximal versus distal style of parenting is one of several useful ways of distinguishing between the care practices of communities that live by different ethics. Another valuable distinction is between types of sensitivity. In the West, sensitivity is equated with a host of caregiving characteristics, including contingent responsiveness to children's signals, as well as promptness, cooperation, availability, and following the child's lead. This interactive style is believed to promote autonomy, because the child perceives herself as in control and competent, certain that caring others are available if the need arises. However, the nature of sensitivity varies across cultures, and this may have implications for self-regulation and the processes associated with its development.

Cameroonian and German mothers, for example, differ in their sensitivity to positive and negative infant signals. Cameroonian mothers are more sensitive to infants' signs of distress, and German mothers, to infants' positive signals (Voelker et al., 1998). Similar differences between non-Western and Western mothers are reported by Friedlmeier and Trommsdorff (1999) and LeVine (2004). LeVine's findings indicate that Gusii mothers of Kenya are more sensitive to their baby's distressed vocalizations than are middle-class U.S. mothers, and that Gusii babies cry less than the U.S. babies. The Gusii practice of maintaining nearly constant contact with babies in the first year of life allows mothers to respond quickly to their infant's distress. Gusii mothers are shocked by videos of American mothers allowing infants to cry, even momentarily. For Gusii mothers, prevention of crying through continuous contact is morally mandated. Yet Gusii mothers show little responsiveness to positive signals. Unlike middle-class U.S. mothers, they do not amplify positive expressions of emotions but turn away from infants who are getting positively excited, so as to calm and soothe them (LeVine, 2004).

Sensitivity in non-Western cultures may be more proactive, with adults and even children anticipating others' distress, or recognizing nascent signs of it, and taking measures to avoid it. There is evidence of this among the Efe, where adults sometimes comfort infants even before they are noticeably upset (Morelli, Henry, & Baldwin, 2002); so too among the Nso (Keller, Yovsi, & Voelker, 2002) and the Guisii (LeVine, 2004). In Japan, preschool teachers emphasize the importance of anticipating children's needs and see the child's role as waiting for the teacher to meet their needs (Rothbaum, Nagoaka, & Ponte, 2005). Anticipatory responsiveness breaks down the child leads/adult follows interactive style, prioritizing less the child's control, and making more ambiguous the distinction between self and other. The U.S. preschool teachers in the previous study reported that anticipation undermined the development of self-expression, self-assertion, and autonomy in young children.

Like parental sensitivity, parental control has different meaning and implications for self-regulation in other cultures. Control includes expressions of warmth in many societies living by ethics of community. For example, Chinese parents and teachers govern—*guan*—children by taking control, directing their behaviors, and placing demands on them (Tobin et al., 1989). *Guan* also means to love and to care for, and it is viewed in a positive light by adults and children alike. Japanese and Korean adolescents associate parental control (*guan*) with warmth and acceptance (Chao & Tseng, 2002). Control for many Asians is rooted in notions of family hierarchy, respect, obligation, and self-sacrifice. In contrast, control for many North Americans is negatively associated with feelings of closeness (measured in terms of cohe-

siveness; Nomura, Noguchi, Saito, & Tezuka, 1995). For them, control is antithetical to self-determination and positive caregiving, because it is rooted in heteronomy, inequality, and restrictiveness.

Because human qualities such as attachment and self-regulation take on very different forms and have different meanings, it should not be surprising that they develop in systematically different ways. In some communities, social development is fostered by distal parenting, sensitive responsiveness, and autonomy fostering practices. In other communities, social development is fostered by proximal parenting, sensitive anticipation, and authoritarian control.

REFLECTIONS ON COHERENCE: CONSISTENCY OR FLEXIBILITY

According to Western theorists, secure attachments and successful self-regulation are predicated on a coherent self. Although all cultures may value self-coherence, we believe there are important differences in the meaning of *coherence* and conceptions of self. Here we review evidence that Western laypersons and researchers emphasize intraindividual consistency across persons, situations, and time, whereas non-Western laypersons and researchers emphasize extraindividual flexibility across roles and contexts (Heine, 2001). Moreover, we attempt to show that theories of attachment and self-regulation are grounded in Western notions of self-coherence that highlight the all important role of autonomy. We also consider how attachment and self-regulation might be understood differently when non-Western notions of self-coherence, which rely much less on notions of autonomy, are adopted (see Table 20.1).

TABLE 20.1. Cultural Differences in Conceptions of Coherence

	Locus	Stability	Process	Central principle/value	One self/ many selves
Western coherence	Intraindividual	Consistency (across time, place, and person)	Internalization, integration	Autonomy	Notion of core authentic self
Non-Western (majority world) coherence	Extraindividual	Flexibility (across time, place, and person)	Balance between demands of different relationships	Community/harmony	Importance of different roles in different contexts

Research on Coherence

In the West, the self is viewed as relatively unchanging across situations and stable across time, and consistency is seen as essential to healthy functioning (Heine, 2001; Suh, 2002). Many Western theories of social functioning are predicated on this notion of self-consistency (see Kitayama & Markus, 1999, for a review). Consistency is much less valued in East Asia, where “an individual’s relationships and roles take precedence over abstracted and internalized attributes, such as attitudes, traits and abilities. . . . It is important for the East Asian self to be able to determine what the role requirements are for a given situation and to adjust self accordingly” (Heine, 2001, p. 886).

Evidence of greater emphasis on internal self-consistency in Western than non-Western communities comes from various quarters. In the West, individual attitudes are typically more powerful predictors of behavior than are social norms (Triandis, 1995). Belief in attitude-behavior consistency is more pronounced among Australians than Japanese—indeed, Japanese are more likely to align their actions with others’ beliefs than with their own (Kashima, Siegel, Tanaka, & Kashima, 1992), and Japanese manifest less susceptibility to dissonance (less consistency between one’s own attitudes and behavior) than do Canadians (Heine & Lehman, 1997).

Whereas, for North Americans, self-coherence is evident in the consistency of underlying attitudes and dispositions, coherence for East Asians is evident in “attunement of the self with the social surrounding. . . . It is this self in a specific social context that predominates in subjective experience” (Kitayama & Markus, 1999, p. 264). There is greater consistency among American than among Korean students’ self-views across social roles, such as son, daughter, and friend (Suh, 2000), and across hypothetical situations (Suh, 2002). Similarly there is more consistency for Americans than for Japanese when making self-descriptions when different people are in the room with them (Kanagawa, Cross, & Markus, 2001), and when they are describing their personal versus public selves (see Kitayama & Markus, 1999).

Underlying different representations of cohesion are differences in attention, perception, and reasoning. Fiske et al. (1998) cite several

studies indicating a tendency toward linear, analytic, decontextualized information processing in the West, and holistic, context-dependent information processing in the East. Eastern thought is often dialectical—in this context one thing is true, whereas in another context the opposite is true, or the middle way is endorsed (Nisbett, Peng, Choi, Norenzayan, & Ara, 2001).

Coherence in Attachment and Self-Regulation Theory

Coherence is a central construct in Western theories of attachment and self-regulation. In addition to entailing consistency between internal psychological characteristics (beliefs, emotions, dispositions, goals, etc.), the coherent self depicted in these theories is autonomous, unified, integrated, and authentic, as opposed to externally driven, inconsistent, fragmented, and false.

In attachment theory, children’s coherence is most evident in their “internal working model”—the stable, integrated set of expectations and experiences pertaining to relationships and the self. A coherent model is one linking attachment and autonomy (i.e., it depicts a caregiver who fosters the child’s autonomy by sensitively responding to needs for security). Adult attachment is assessed by the Adult Attachment Interview, which relies on the notion of coherent discourse—the consistency, clarity, succinctness, and most importantly, the meaningfulness of the attachment narrative. Individuals must fully own and integrate positive and negative aspects of experience for their narratives to be coherent. Autonomy allows for a sense of ownership of inner experience and integration of the narrative. This is evident in the term used for the most secure and coherent adult attachment category—*autonomous* (Fonagy, 1999; Main & Goldwyn, 1998).

In Western self-regulation theory, coherence is typically conceptualized as integration. It is sometimes operationalized as correlations between different self-regulatory constructs (involving emotional control, compliance, delay, etc.), or by one construct (compliance) over different situations or over time (Kochanska & Murray, 2000). Little attention is devoted to contextual factors. Self-coherence and successful self-regulation emerge when the individual freely and autonomously chooses goals, because such goals can be fully integrated with

other self-endorsed goals (Baumeister & Vohs, 2003; Eisenberg, Smith, et al., 2004; Ryan & Deci, 2000b).

More recent theories of self-regulation, particularly theories of social cognition in adults (see Cervone & Shoda, 1999, for reviews), place greater emphasis on situational differences than do the self-regulation theories focused on in this chapter. However, these theories depict situations and perceptions of situations as modifiable by self (Cervone & Shoda, 1999; Heine, 2001), they do not depict situations as part of self, and they link self-regulation with autonomy. These are quintessential features of Western self-coherence.

A very different notion of coherence in non-Western cultures is not predicated on ethics of autonomy, but on ethics of community, and, more specifically, on an emphasis not only on harmony, but also on respect, duty, obligation, and proper demeanor. Unlike values associated with autonomy (choice, freedom, agency), values associated with community are closely tied to specific persons (role relationships), places, and situations (public/formal vs. private/informal). They are meaningless when stripped of role and context. What makes the self coherent is not internalization, but coordination with others in the community. Coherence is less predicated on an independent, unitary, authentic sense of self, and more on an interdependent sense of self that is always mindful of particular others and particular contexts in which the self is situated: "Normative demands . . . [are] perceived to be part and parcel of the self" (Kitayama & Markus, 1999, pp. 265–266).

The implications for attachment and self-regulation are profound. When coherence is defined in terms of community and harmony, relationships do not primarily serve to foster the self's goals, but rather to determine the self's roles. Without roles there is no self-coherence. As a result, coherence is less likely to be experienced or expressed as consistency. Consistency in self-regulation in different situations (public and private), or with different persons (ingroup and outgroup members), would not be seen as a marker of authenticity of self, but rather as a sign of incoherence and immaturity. Such behavior ignores the press for modifying one's behavior to accommodate to interpersonal and contextual demands (Fiske et al., 1998; Heine, 2001; Kitayama & Markus, 1999).

The Role of Balance in Coherence

Despite their emphasis on consistency, Western theorists are very focused on internal conflicts. Conflict is central to psychodynamic theory and was a major concern of behaviorists, including cognitive behaviorists. Healthy development is seen as the ability to link or integrate competing desires. This is seen in attachment theorists' emphasis on the trade-off between the desire for attachment and the desire for autonomy (which, early in life, is manifested as exploration). The more secure the attachment, the more the child ventures outward, and the more the child ventures outward, the more she experiences fear and seeks security/attachment figures. Optimal functioning occurs when these competing needs are balanced and integrated. Self-regulation theorists' central thesis is very similar: that there is a trade-off between socially desirable behaviors (attention, compliance, delay of gratification) and autonomy, and optimal functioning represents the balance and integration of the two. Autonomy is seen as leading to compliance ("committed" compliance), and compliance is seen as setting the stage for autonomy. In both theories, the key phenomena of interest (attachment and aspects of self-regulation) are inextricably linked with autonomy; the quality of the linkage determines the coherence of the organism. Both theories' depiction of autonomy as the phenomenon with which all other processes must be balanced stems from the assumption of an independent selfway, and the equating of coherence with internal, autonomous integration of different aspects of self.

Conceptions of balance in non-Western communities have little to do with autonomy. The attachment balance in these communities is between attachment and role responsibilities. Harwood and colleagues (1995) emphasize the balance between closeness and "respectful attentiveness," and investigators focused on Japan emphasize the balance between closeness and formal, role-prescribed behavior (Kitayama & Markus, 1999; Rothbaum & Kakinuma, 2004). The central conflict involves different roles and contexts more so than different internal desires. The individual who has secure intimate relationships is more capable of fulfilling formal duties and role responsibilities, and of balancing different relationships (Heine, 2001; Rothbaum & Kakinuma, 2004). Similarly, self-regulation is a balance between soft-

hearted, self-sympathetic behavior and hard-hearted, disciplined behavior; the ability to know with whom and when to engage in each type of behavior constitutes self-coherence and effective regulation (Kitayama & Markus, 1999).

Western conceptions of attachment and self-regulation, which are predicated on an independent selfway, treat autonomy as central, and community and context as relatively peripheral. Non-Western conceptions, which are predicated on an interdependent selfway, treat the ability to act appropriately with different persons in different situations as central. Coherence in this case is located at the interface of self and context rather than internally. It is based less on free will, individual choice, and autonomous ownership of different ways of being, and more on fitting the self (different aspects of self) with contextual realities. Whereas autonomy is the connective tissue that allows for coherence in the West, context appropriateness is the connective tissue that allows for coherence in many non-Western communities. In the latter communities, coherence of attachment is evident when children know with whom and in what situations they can be intimate and dependent, and with whom and in what situations they must be reserved and accommodating. The situated self is always mindful of the particular persons and settings in which she is embedded.

CONCLUSION: JUST TWO PATHWAYS?

In this chapter we have taken to task Western theories of attachment and self-regulation for their assumption of a single pathway to valued forms of security and regulation. However, we may be vulnerable to a similar charge: The assumption of two distinct pathways may not do justice to the diversity of models of attachment and self-regulation, as well as to underlying conceptions of coherence that characterize human functioning worldwide.

There are competing views about the number of pathways that should be entertained in cultural studies: Some theorists feel more strongly than we do about the pervasiveness of two relatively distinct pathways (e.g., Greenfield et al., 2003). These investigators tend to lump together diverse cultures into two relatively separate pathways—typically, those from North America, and Northern and Western Eu-

rope, and those from the rest of the world. Other theorists accept the two-pathway paradigm but argue for subdivisions within them, sometimes as hybrid forms that combine elements of both categories (e.g., Kağıtçıbaşı, 1996). Still others leave open the possibility of new, as yet unidentified pathways, while acknowledging the substantial evidence currently supporting the two-pathway view (e.g., Saraswathi, 2003). Finally, there is another set of views antithetical to the ones noted that question any press to identify larger pathways; for these theorists, each community is unique and cannot meaningfully be grouped with any other along comprehensive dimensions (e.g., Gergen, Gulerce, Lock, & Misra, 1996).

In this chapter, our assumptions frequently conform to the first of these views—two relatively distinct cultural pathways. Yet we believe that science is best served when researchers leave open the possibility of many pathways, not just two. We described the majority world as living by ethics of community without strong justification for combining such diverse communities in a single category, and we sometimes defined these communities in terms of what they do *not* value (e.g., autonomy). When we defined these communities in terms of what they do value—harmony, community, accommodation—we did not acknowledge that these communities may differ in how they make sense of these constructs. We need to accept the possibility of new pathways as well as “subdivisions” within the two prevailing pathways.

Our understanding of attachment and self-regulation will be hindered, not advanced, by searching for *the* alternative to Western theories of these constructs. It will also be hindered if we resist attempts to identify “ways of being” common to people of different communities, and if we are unwilling to cluster these communities based on these qualities. Clustering has served to highlight some of the most important and valuable distinctions that we have developed in cultural studies (e.g., individualism–collectivism; independence–interdependence), and it is an indispensable tool for making sense of the remarkable variation that characterizes humanity. The problem with these distinctions is that they tend to be used in ways that oversimplify; the solution is to resist that tendency and to be continuously mindful of exceptions that elucidate the complexities.

We began this chapter by considering one community—the Efe hunters and gatherers of the Democratic Republic of Congo—that challenges Western assumptions about attachment and self-regulation. We might have talked about them in a way that implied they best fit the interdependent pathway, living by ethics of community. But we are not completely convinced of this characterization. The Efe are self-reliant and independent in ways consistent with qualities typically associated with people who live by ethics of autonomy. This may be in part because of the way they make a living—hunting and gathering (Barry, Bacon, & Child, 1959). They are also an emotionally expressive people—expressing emotions publicly for all to witness. Gilda A. Morelli remembers with great amusement the sheepish look on Kebe’s face as the sounds of his angry wife grew louder as she approached our village. It appears that the moment she heard that Kebe was visiting with us instead of hunting, she expressed her great annoyance with him by yelling loudly and gesticulating widely, and continued to do so on her march from her camp to our village, about a kilometer. The seemingly unrestrained expressions of emotions such as anger are quite common among the Efe, and it took some time for us to get use to this.

Although this portrayal may be construed as an example of the need for a subdivision of the interdependent pathway, we would like to consider the possibility that it represents a third pathway, in which self–other tensions are navigated in a way not characteristic of the two identified pathways. Among the Efe, interdependence seems so profound that it is taken for granted—a given—and little appears to threaten it in any obvious way—certainly not acts that call attention to self or emphasize the distinct and uniqueness of self. Perhaps a closer study of acts that threaten survival, literally, may help us better understand the Efe selfway. We do not have a readily available script to describe this selfway, but we think it is worth considering ways to do so. We hope that this chapter contributes to this endeavor and, by doing so, points to other possible pathways to attachment and self-regulation.

NOTES

1. Gilda A. Morelli has lived and worked with the Efe of the Ituri Rain Forest of the Democratic Republic

of Congo since 1981. The vignettes about them were taken from her field notes spanning over two decades. The names used are typical Efe names, but there is no correspondence between the name and the persons described in the scene. The Efe make a living by hunting and gathering forest foods, and working in local villages in exchange for agricultural goods such as rice and peanuts. To some they are known as “Pygmies” but this is a term they find pejorative.

2. In this part of the chapter, the theories, perspectives, and research referenced (unless noted) were developed primarily in English-speaking (United States, Canada, Australia, and New Zealand) and Western and Northern European communities, and are referred to by most as “Western” theories. We typically do not use this qualifier for the sake of simplicity in the sections on self-determination theory, attachment relationships, and self-regulation.

3. We juxtapose vignettes describing Efe children’s experiences with accounts of children’s experiences described by Western theorists concerned with attachment and self-regulation. These theorists assume that the experiences they describe are common to all children. We hope the vignettes call attention to differences, as well as to similarities, between what occurs in one community and what is assumed to be universal.

4. Eisenberg and Spinrad (2004) define *emotion regulation* as “the process of initiating, avoiding, inhibiting, maintaining, or modulating the occurrence, form, intensity, or duration of internal feeling states, emotion-related physiological, attentional processes, motivational states, and/or behavioral concomitants of emotion in the service of accomplishing affect-related biological or social adaptation or achieving individual goals” (p. 338). This definition is like that used by Grolick, McMenemy, and Kurowski (1999), but other conceptualizations exist (e.g., Cole, Martin, & Dennis, 2004).

5. Recent research examines how psychological processes such as temperament or effortful control moderate or mediate the relation between security of attachment or maternal interactive style and behavioral regulation (e.g., Feldman, Greenbaum, & Yirmiya, 1999; Kochanska & Knaack, 2003). We do not review this research, because the findings do not alter the gist of what we have to say.

6. Much of the research we consider examines maternal interactive style in structured situations, most often in a laboratory setting, which asks the mother to play with her child, teach her child how to work a toy or play a game, or to get her child to do a task such as “cleanup.” Children’s emotional expression is usually observed in situations that are frustrating (waiting to get a toy or food) or upsetting (child is restrained). Children’s compliance is typically assessed in cleanup tasks or delay tasks with mother present, conscience, in terms of compliance in the absence of an adult, and responses to items that assess the “moral self” or to hypothetical moral situations.

7. A similar distinction is made between individual-

istic and collectivistic societies, with people in individualistic societies characterized as independent, and those in collectivistic societies, as interdependent.

8. The expression "majority world" is used in the remainder of the chapter to refer to the overwhelming majority of the world's cultures and the vast majority of the world's population, including, but not limited to, Asian, African, southern and eastern European, and Hispanic/Latino communities. We do not believe that there is homogeneity between or within these countries, but they have in common being neglected by prevailing theories and evidence, which are based overwhelmingly on studies of Western cultures.

9. What people notice and attend to includes appraising the situation, which contributes significantly to their emotional experience and expression (Mesquita, 2003).

CHAPTER 21

Biocultural Co-Construction of Developmental Plasticity across the Lifespan

SHU-CHEN LI

Historically, the nature–nurture controversy has been debated for centuries, dividing the fields of behavioral and neurobiological development (for reviews, see Meaney, 2001; Rensberger, 1983). On the nature side, nativists argue that human development is determined by innate factors, such as genetic endowment and brain maturation. On the nurture side, the empiricists see development as the result of experience and learning, and that individuals at the beginning of life are more or less capable of acquiring what the environment provides. Although interactionism has also been proposed as an alternative to steer research and public views away from the simple but false dichotomy, the nature–nurture debate continues and has even intensified since the publication of two working drafts of human genome sequence at the turn of the 21st century (International Human Genome Sequencing Consortium, 2001; Venter et al., 2001).

Instead of polarizing toward either end, the aim of this chapter is to approach the age-old nature–nurture debate through the lens of

biocultural co-constructivism (Baltes, Rösler, & Reuter-Lorenz, 2006; Li, 2003; Li & Lindenberger, 2002). Although there are certainly biologically based limits on behavior and cognition, it is also important to consider brains as open, dynamic information processors that are receptive to sociocultural influences. The fundamental proposition of biocultural co-constructivism is that contextualized experiences shape the functional dynamics of brain–behavior reciprocity. Building on general, species-typical neurobiological predispositions that are evolved through brain evolution, during ontogeny brains obtain information about the world and are shaped by it through embodied and embedded experiential tuning. The term “embodiment” as used here refers to the notion that brains sense and perceive stimulations from the external world through bodily sensory and motor processes, whereas the term “embedding” refers to the fact that most of the information that brains process is socioculturally contextualized (cf. A. Clark, 1999, for a review of embodiment; see

Hatano & Wertsch, 2001, for review of socio-cultural contextualization). Therefore, lifespan development of behavior and cognition should not automatically be considered solely as the maturation or aging of basic information-processing mechanisms and their neurobiological substrates.

Conceptions of environmental, cultural, and behavioral factors interacting with the biological inheritance of human development have long philosophical traditions. For instance, Tetens (1777) assigned extraordinary plasticity to human nature, thus stipulating opportunities for environmental, cultural, and individual regulation during life ontogeny. At the evolutionary phylogenetic level, St. George Jackson Mivart (1871) suggested that behavioral changes and adaptation precede and affect natural selection. Among modern behavioral development researchers there is the consensus that individual ontogeny is hierarchically organized within an open developmental system that has multiple levels of contexts (e.g., the endogenous neurobiological context and the exogenous family, school, and sociocultural contexts). Consequently, developmental phenomena need to be investigated by jointly considering interactions between endogenous and exogenous processes at various levels (e.g., Alexander, 1969; Anastasi, 1958; Baltes, 1979; Baltes & Singer, 2001; Bronfenbrenner, 1979; Bronfenbrenner & Ceci, 1994; Gottlieb, 1976, 1998; Magnusson, 1988, 1996; Schaie, 1965).

A general awareness of co-constructive notions in and of itself is, however, not enough to resolve the nature–nurture and brain–behavior controversies. The integration of experiential and cultural influences into the day-to-day research practices of neurosciences requires that reciprocal interactive processes implementing biocultural co-construction of brain, mind, and behavior at different levels be further specified. Lacking specifications of such cross-level reciprocal interactions, in part, has been one of the reasons why the nature–nurture debate has continued, because mechanisms of mutual influences between biology and culture during the processes of brain evolution and ontogeny are not made explicit (cf. Ingold, 1998; King, 2000). Cross-level frameworks that explicate reciprocal interactions of developmental plasticity across different levels and time scales are thus needed to foster integration of research from related subfields of developmental and life sciences.

BEYOND RESOURCES: CULTURE'S ACTIVE ROLE IN DEVELOPMENT

Culture has most commonly been conceived as a socially inherited body of man-made material artifacts, knowledge, values, and beliefs accumulated from the past of a given social group that functions as resources to coordinate current human life among individuals and between individuals and the physical environment (e.g., D'Andrade, 1996; Herskovitz, 1948; Tylor, 1874). If only the “resource” aspect is emphasized—as is the case in most generic definitions—then culture is merely the static and passive product of past civilization that is utilized to support the current ways of human life. Some scholars criticized the inadequacy of such notions of culture that view it as merely the supplement of biologically based capacities. The main concern of these criticisms is that a static resource view of culture could not address the intertwined relations of culture and biology in the course of human phylogeny and individual ontogeny (e.g., Geertz, 1973).

Culture as Collective Social Processes

The accumulation of cultural resources can be considered as a dynamic process that involves the so-called “ratchet effect” or “cumulative cultural evolution” (Tomasello, 1999). During such a process, individuals of a given cultural group progressively made modifications to the inherited body of cultural resources. Consequently, the inherited cultural resources become more complex, encompassing a wider range of adaptive functions. Furthermore, at the ontogenetic level, ongoing collective social dynamics (i.e., face-to-face interpersonal interactions, other social interactions derived from them, and shared intentionality) constructs the shared social reality in present societies (Berger & Luckmann, 1967; Searle, 1995). The process aspect of culture is particularly emphasized in recent research on cognitive engineering of the workplace and interactive minds (e.g., Baltes & Staudinger, 1996; Hutchins, 1995). For instance, the routines, habits, and performance criteria of a given workplace are not always static across even relatively short periods (i.e., weeks or months); rather, they are constructed online with the intentions, thoughts, and behaviors of members in the group affecting each other to shape the collective “working cul-

ture.” Bringing the collective social processing aspect of culture to the foreground makes obvious the social interactions taking place in the individual’s proximal developmental context as part of the processes mediating cultural influences on brain, cognitive, and behavioral development.

Culture as Developmentally Relevant

One other somewhat implicit but consistent feature in modern conceptions of culture is its relevancy for individual development. For instance, Williams (1973) pointed out that many of these notions arise from terms referring to processes that help organisms *grow*. For instance, culture has been considered as an integral part of the “garden for development” (Cole, 1999) or “developmental niche” (Gauvain, 1995, 1998; Super & Harkness, 1986), that edify individual development to minimize the distance between the individual’s attained and potential levels of performance (Vygotsky, 1978). Highlighting developmental relevancy as distinct from the resource and process aspects of culture emphasizes the active role and function of cultural resources, together with the social processes generating them in individual development. Different cultures (or subcultures within a culture) can differ in the level of resources (or opportunities), as well as constraints, they put forward for individual development in profiles of behavioral expressions, in the constellations and processes of interactive minds, and in their receptivity to modifications by individual behaviors and new technological advances (Baltes & Singer, 2001).

To explicitly consider the dynamics of biocultural co-constructive influences on lifespan development, the three distinct but related aspects of culture (resource, process, and developmental relevancy) need to be simultaneously highlighted. Culture, thus, can be reconsidered as ongoing collective social processes that generate social, psychological, linguistic, symbolic, material, and technological resources that influence human development via reciprocal mechanisms feeding back into individuals’ moment-to-moment microgenesis, lifespan ontogeny involving mind–brain interaction, and human phylogeny involving culture–gene coevolution (Li, 2003). Defined as such, culture is not just the passive product of socially inherited resources of human civilizations, such as

tools, technology, language, knowledge, art, customs, values, and beliefs that are accumulated over the past. Rather, it is the “cogenerator” of culture–gene coevolution during human phylogeny in the long run, and together with behavioral, cognitive, and neurobiological plasticity, it is the active “coproducer” of brain, cognitive, and behavioral development during individual lifespan ontogeny.

RELATIVE CONTRIBUTIONS OF BIOLOGY AND CULTURE ACROSS THE LIFESPAN

Human development reflect the interactions between three classes of processes: (1) species-typical neurobiological and cultural evolutionary processes; (2) normative, age-graded, socialization-typical ontogenetic processes with which the individual acquires shared pragmatic knowledge (e.g., basic language and arithmetic skills) of a given sociocultural group; and (3) idiosyncratic (non-normative) influence of person-specific professional expertise and skills that result, at least in part, from the individual’s self-selected and constructed personal life experiences and history (Li & Freund, 2005; Baltes & Smith, 2004). Developmentalists and lifespan researchers generally appreciate the fact that both biological and socialization processes contribute to individual ontogeny, and that multiple classes of processes at different levels affect development. However, the dynamical shift in the relative contributions of biology and culture across different periods of life is a topic that is rarely considered. Baltes (1997) made an effort to propose a framework for considering the interplay of biology and culture in lifespan development by specifying three principles (see Figure 21.1).

The first principle suggests that biology-based plasticity decreases after maturity. This is presumably due to the lack of evolutionary selection pressure on survival in the postreproductive phase of life; therefore, beneficial evolutionary selection affording optimal functioning (in the sense of basic biological potential) was less operative for later periods of life as genetic evolution proceeded. Second, more and more culture is required to extend human development to higher levels of functioning and older ages. By increases in cultural resources, for instance, via the process of cumulative cultural evolution (Tomasello, 1999), the

FIGURE 21.1. Schematic representation of principles about the dynamic interplay between biology and culture across the lifespan. Adapted from Baltes (1997). Copyright 1997 by the American Psychological Association. Adapted by permission.

window of ontogenetic time and opportunities can be extended and expanded for more individuals into older ages. However, at the same time, it should also be kept in mind that the cultural conditions and resources required for reaching increasingly higher levels of functioning and older ages increase as well. The third principle states that cultural impact or efficiency varies by age. Specifically, as decline in neurobiological functions limits the effectiveness of cultural influences, the efficacy of cultural resources decreases with increasing age during adult development. Thus, it takes more and more resources and support to produce the same level of cognitive performance in old age. Examples drawn from lifespan cognitive devel-

opment are reviewed in the following section to illustrate these principles.

Differential Trajectories and Dynamic Organization of Intellectual Abilities

The differential trajectories and dynamic organization of different aspects of intellectual abilities across the lifespan are two illustrations of the dynamic interplay between biology and culture in the domain of cognitive development. Dual-component theories of intelligence distinguish between fluid cognitive mechanics, which reflect the operations of the relatively more neurobiology-based information-processing mechanisms (e.g., processing speed, working memory, and attention), and crystallized cognitive pragmatics (e.g., language and practical skills), which are the outgrowth of experience- and culture-based knowledge (e.g., Baltes, Lindenberger, & Standing, 1998; Cattell, 1971; Horn, 1968). Cross-sectional age gradients and longitudinal age trajectories (e.g., McArdle, Ferrer-Caja, Hamagami, & Woodcock, 2002) of these two domains of intellectual abilities generally show a lead-lag pattern across the lifespan. As an example, empirical cross-sectional age gradients, covering the age range from 6 to 89 years plotted in Figure 21.2 show that the more biology-based fluid cognitive mechanics develop and decline earlier than the more culture-based crystallized cognitive

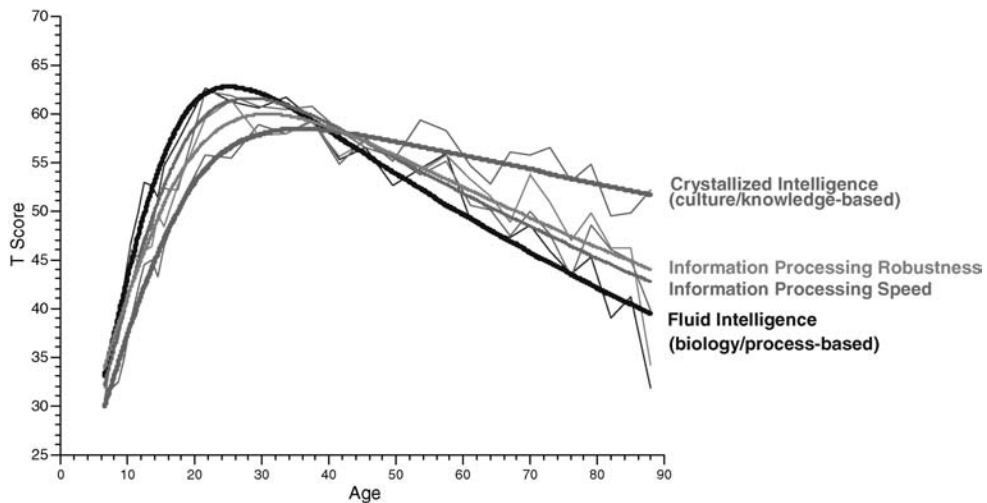

FIGURE 21.2. Fitted empirical age gradients of two broad domains of intellectual abilities along with gradients of basic processing speed and processing robustness. Adapted from Li et al. (2004). Copyright 2004 by Blackwell. Adapted by permission.

pragmatics. The maximum performances of cognitive mechanics and the associated basic information-processing mechanisms (e.g., processing speed and robustness) are achieved by individuals in their mid-20s, whereas the maximum performances of cognitive pragmatics (e.g., culture-based verbal knowledge) are achieved by individuals in their mid-40s and remain stable until 70 years of age, at which point they also decline (Li et al., 2004).

Applying Baltes's (1997) framework to intellectual development, a further proposition can be made. During childhood and old age, neurobiological influences on behavior and cognition are strong; thus, individual differences are affected relatively more by species-typical neurobiological constraints. In adulthood, when the optimal efficacy of neurobiological mechanisms is reached and maintained, individual differences are affected relatively more by socioculturally contextualized experiences that individuals accumulate through their personal life histories (see Figure 21.3). During life periods when there are strong biological constraints on basic information-processing mechanisms underlying the acquisition and expression of culture-based knowledge, the different facets of intelligence and their constituent basic information-processing mechanisms are expected to correlate more highly with each other than in periods when neurobiological efficacy functions at (or above) threshold level.

This proposition suggests that variations in the relative contributions of biology and culture are contributing factors to the differentiation (diversifying) and dedifferentiation (dediversifying) of intellectual abilities, which is an

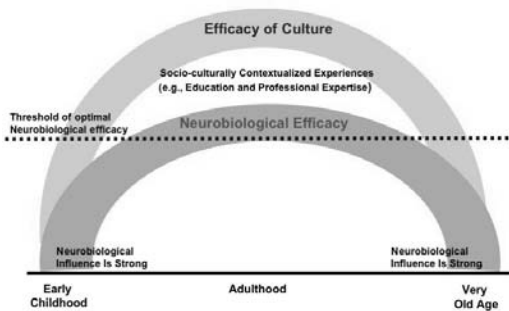

FIGURE 21.3. Schematic representation of the relative contributions of neurobiological constraints and sociocultural contextualized experiences on individual differences across the lifespan.

empirical phenomenon that has been discussed in cognitive-developmental psychology since the 1940s (e.g., Balinsky, 1941; Baltes, Cornelius, Spiro, Nesselroade, & Willis, 1980; Garrett, 1946; Reinert, 1970). This proposition is further supported by recent cross-sectional and longitudinal findings. For instance, in a cross-sectional lifespan sample, the amount of covariance shared among the more biologically based aspects of basic cognitive processes (e.g., indicated by information-processing speed of visual and memory search, response competition, and choice reactions), the more biologically based intellectual abilities (memory, reasoning, perceptual speed), and the more culture-based abilities (e.g., verbal knowledge and verbal fluency) were observed to be higher at both ends of the lifespan than in adulthood (see Figure 21.4, which plots the lifespan functions of correlations between basic information-processing speed and two broad domains of intellectual abilities separately). Applying a dynamic structural modeling technique (i.e., statistical methods that analyze the relations between age-related processes of change) to the longitudinal data from the Berlin Aging Study, Ghisletta and Lindenberger (2003) demonstrated that aging-related declines in the pragmatic knowledge of intelligence (indexed by culture-based verbal knowl-

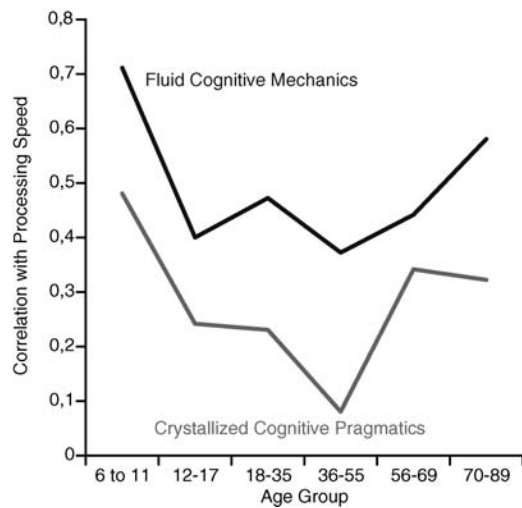

FIGURE 21.4. Stronger correlation between basic information-processing speed and two facts of intellectual abilities in childhood and old age than in adulthood. Adapted from Li et al. (2004). Copyright 2004 by Blackwell. Adapted by permission.

edge) are correlated with changes in the cognitive mechanics (indexed basic cognitive processing speed), with the cognitive mechanics being the leading factor. This suggests that, in old age, neurobiological correlates of declining basic information-processing speed constrain the expression of socioculturally acquired knowledge.

CROSS-LEVEL RECIPROCAL INTERACTIONS OF DEVELOPMENTAL PLASTICITY

Parallel to the concept of lifespan variations in the relative contributions of biology and culture to development, a related more recent framework focuses on the reciprocal interactions of developmental plasticity across levels (Li, 2003). As schematically shown in Figure 21.5, an integral whole of biocultural influences on lifespan brain and behavioral development can be implemented through reciprocal interactive processes and developmental plasticity that are simultaneously embedded within three timescales (i.e., phylogenetic, ontogenetic, and microgenetic times) encompassing

multiple levels (i.e., sociocultural, behavioral, cognitive, neurobiological, and genetic). Individual ontogeny throughout life in this framework is considered as a dynamic process that is cumulatively traced out by moment-to-moment experiences and activities taking place through reciprocal interactions across the behavioral, cognitive, and neurobiological levels on the microgenetic timescale. These moment-to-moment microgenetic events are couched within (1) the proximal developmental context involving culturally embedded social interactions and situations on the lifespan ontogenetic timescale and (2) the distal context of culture-gene coevolution occurring on the long-term phylogenetic timescale.

More specifically, the framework of cross-level dynamic biocultural co-constructivism particularly highlights the reciprocal influences between interactive processes and developmental plasticity at different levels occurring on different timescales. This is depicted in Figure 21.5 by the dynamic joining of the feed-downward and feed-upward processes across the different levels and timescales, thus generating an integral whole of biocultural co-

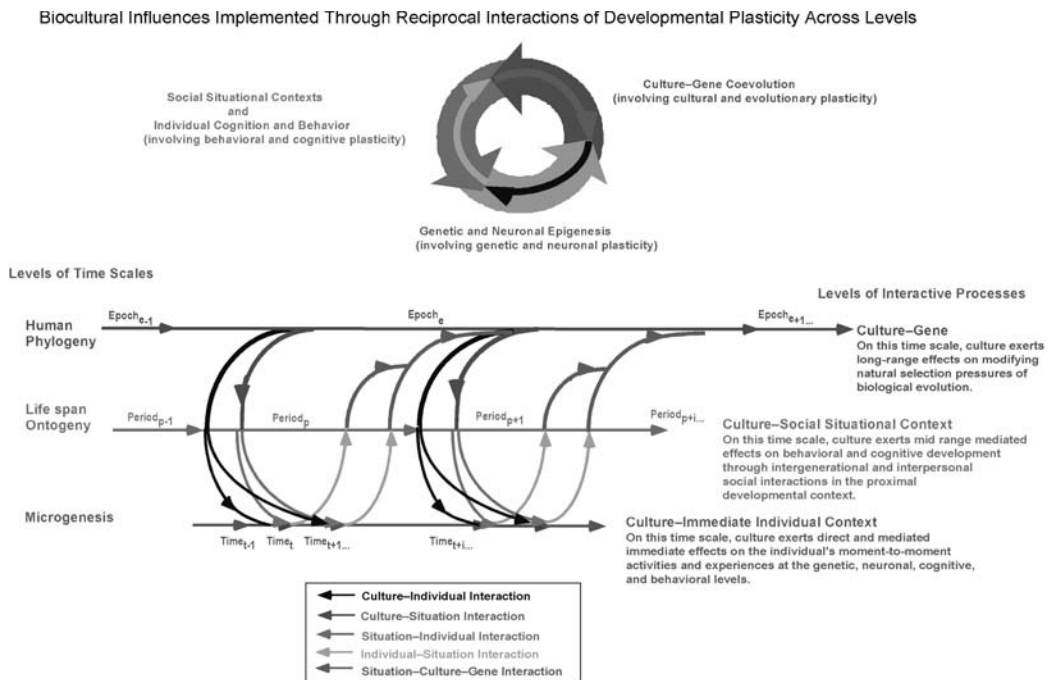

FIGURE 21.5. Schematic representation of biocultural co-construction of developmental plasticity across levels. Adapted from Li (2003). Copyright 2003 by the American Psychological Association. Adapted by permission.

constructive influences on human development. Feed-downward influences denote cultural factors arising from human phylogeny affecting individual moment-to-moment experiences at the behavioral, cognitive, and neurobiological levels. Feed-upward influences represent neurobiologically implemented individual cognition and behavior that contribute to collective social dynamics and cultural change.

Regarding feed-downward influences, *culture–individual interaction* highlights the direct influences of culture on behavior and cognition through the individual’s firsthand personal experiences with the physical or formal properties of culture-specific artifacts and symbolic tools evolved over the human phylogenetic time. The phonological and orthographical properties of languages are examples of formal characteristics of culture-specific linguistic environments affecting the perceptual and neuronal aspects of language processing on the timescale of moment-to-moment activities. Other than directly influencing the individual, culture may first shape the social contexts and daily situations within which individual development takes place through *culture–situation interaction*. Culture-specific social customs, values, and concepts about the individual’s identity are some examples. Through *situation–individual interaction*, the influences of culturally embedded social interactions (e.g., parent–child interaction, schooling, and peer interactions) mediate cultural impacts on the individual’s moment-to-moment experiences. As for feed-upward influences, processes of cultural changes involve *individual–situation interaction* that cumulatively integrates moment-to-moment experiences at the genetic, neuronal, cognitive, and behavioral levels into an individual’s ontogenetic history. Subsequently, processes of collective social dynamics played out in the individual ontogenetic histories of a society’s members generate further culture–gene coevolution (Durham, 1991).

Contrary to the nativist view of innate and encapsulated genetic and neurobiological processes, across various subfields of life and developmental sciences there is a clear, reemerging zeitgeist of co-constructive conceptions that are accompanied by much recent empirical support for developmental plasticity at different levels. The remaining sections of this chapter review empirical evidence of developmental plasticity at different levels and exam-

ples of biocultural co-construction to illustrate these mechanisms.

Evolutionary Plasticity

It has recently been argued both on empirical and theoretical grounds that genetic programs and brain organizations reflect the socio-cultural basis of evolution. The conventional coevolutionary theory has been extended by postulating a set of mediating mechanisms called “niche construction” to relate biological evolution and cultural changes to each other (Laland, Odling-Smee, & Feldman, 2000). Central to the concept of niche construction is the capacity of organisms and individuals to modify and construct the sources of natural selection in their environment via (1) learning and experience-dependent processes during individual ontogeny, and (2) processes of cultural change on another scale. For instance, the dairy farming culture selects for adult lactose tolerance and leads to populations in dairy farming societies with a higher percentage (i.e., more than 90%) of lactose absorbers in comparison to the percentage of lactose absorbers (i.e., less than 20%) in societies without dairy farming (Aoki, 1986; Feldman & Cavalli-Sforza, 1989).

A more recent study found evidence in support of a gene–culture coevolution between cattle milk protein genes and human lactase genes. The geographic patterns of variation in genes encoding the most important milk proteins in 70 native European cattle breeds showed substantial geographic coincidence with present-day lactose tolerance in Europeans. The diversity in cattle milk genes is higher in north-central Europe than in southern Europe and the Near East, and, correspondingly, lactose tolerance is higher in northern Europeans (Beja-Pereira et al., 2003).

Behavioral and Cognitive Plasticity

As for developmental plasticity at the behavioral and cognitive levels, various theories in the field of developmental psychology have emphasized the malleability of behavior and cognition by contextualized experiential factors (see Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000). For instance, Vygotsky (1978) had already emphasized the role of social interactions in proximal developmental contexts, such as parent–child relations,

peer relations, and schooling in promoting an individual's attained level of development toward a higher level of potential. More recently, sociocultural contextual approaches (e.g., Cole, 1999; Gauvain, 1995) have focused more specifically on cultural influences affecting these social interactions and their subsequent mediated effects on individual development. In a related but different vein, rather than focusing on cultural influences at a higher level, the relationship contextual approach (e.g., Reis, Collins, & Berscheid, 2000) examines fine-grained details (e.g., emotional and cognitive aspects) of different types of interpersonal relationships and their impact on child development. Still others focus on the linguistic environment as a main facet of culture-specific social interactions in an individual's proximal developmental context (e.g., K. Nelson, 1996). Cross-cultural studies on parenting style (Bornstein, Tal, & Tamis-LeMonda, 1991) found that differential emphases on interpersonal versus object orientation that were mediated through parent-child interactions in the Japanese and American cultures, respectively, affected the types of games and languages at which toddlers performed well in these two societies.

At the cognitive level, a series of recent cross-culture studies have demonstrated that different cultures foster different cognitive styles that, in turn, may affect the basic perceptual, cognitive (e.g., Kitayama, Duffy, Kawamura, & Larsen, 2003; Nisbett, Peng, Choi, & Norenzayan, 2001), and social attributional (Miyamoto & Kitayama, 2002) processes. As for cognitive plasticity across the lifespan, memory-training studies showed that older adults (ages 60–80) still displayed a fair amount of cognitive plasticity in improving their memory performance after training (Baltes & Kliegl, 1992) and that in very old age (i.e., age 80 years and older), marginal cognitive plasticity was still preserved (Singer, Lindenberger, & Baltes, 2003). However, the relative extent of cognitive plasticity was much more limited in old adults, in comparison both to young adults and to children. In a lifespan study of memory plasticity, Brehmer, Li, Müller, van Oertzen, and Lindenberger (in press) observed that the amount of memory performance gain after extensive memory training was highest in young adults (20–25 years), followed by school-age children (9–12 years), then older adults (65–78 years).

Neural and Genetic Plasticity

At the neuronal level of analysis in the field of neurobiology, behavior- and experience-dependent neuronal plasticity have attracted much research attention since Hebb's (1949) proposal of associative synaptic strengthening (i.e., the concept and later discovered phenomenon—neurons that fire frequently together wire together). For instance, it has been demonstrated that the brains of rats reared in environments affording broader ranges of experiences also show more complex synaptic structure with more synapses per neuron, than rats reared in less stimulating environment (e.g., Greenough & Black, 1992; for review, see Grossman, Churchill, Bates, Kleim, & Greenough, 2002; Rosenzweig, 1996). In humans, it was demonstrated that the overall cortical gyral patterns (patterns of brain gyral/sulcal relationship), though in part affected by genes (e.g., Pennington et al., 2000), may also be influenced by experiential factors (Bartley, Jones, & Weinberger, 1997). Another example involves the amygdala, a brain region very much implicated in social-cognitive developmental disorders (e.g., autism) and sometimes referred to as the “innate module” of social cognition (Baron-Cohen, 1995). Contrary to the innate notion, although the amygdala develops relatively early in human gestation (i.e., embryonic days 30–50), its separate nuclei do not start to differentiate until after birth, suggesting plasticity in the amygdala's responses to experiential influences (Kordower, Picinski, & Rakic, 1992). Building on such evidence, some researchers have proposed concepts such as “neural constructivism” (Quartz & Sejnowski, 1997) or experience-induced neural plasticity (C. A. Nelson, 1999) to consider representational features of the synaptic connections as built from dynamic interactions between neural growth mechanisms, on the one hand, and experience-derived neural activity on the other.

Regarding developmental plasticity at the genetic level, there is a recent shift from the traditional view of unidirectional gene → protein information flow (Crick, 1958) to a probabilistic-epigenetic framework (Gottlieb, 1998). The key concept of this framework is bidirectional interactions among genes, neuronal activity, behavior, and environment. Environmental and experiential influences on genetic activities and expressions have been found in various studies (see review in Gottlieb,

1998). Of particularly interest here is the finding of maternal style modulating genetic effects on the offspring's reactions to stressors. Genetically highly reactive rhesus monkey infants raised by especially nurturant females exhibited much less deficit in early exploration and less accentuated responses to mild stressors than were otherwise typical for genetically highly reactive infants raised by normal or highly reactive females (Suomi, 1999).

Cortical Plasticity across the Lifespan

One important but less emphasized aspect of the evidence on plasticity is that neural plasticity occurs even after maturation, beyond infancy and early childhood (see C. A. Nelson, 2000, for review). Regarding plasticity during early development, accumulating data suggest that the functional specialization of the neocortex is established through subsequent epigenetic interactions with the immediate experiential context (Changeux, 1985; Edelman, 1987; Johnson, 2001; Kolb & Whishaw, 1998). Thus, experiential influences leave traces in developing brains capturing developmental effects that accumulate through the individual's moment-to-moment activities and experiences. For instance, it has been demonstrated that face processing is less localized or specialized (i.e., not as differentiated) in infants than in adults. In infants, face processing involves both left and right ventral visual pathways, whereas in adults, face processing primarily involves the right ventral visual pathway. Whereas adult brain activity shows specific sensitivity to upright human faces, no such sensitivity for face orientation is observed in young infants (de Haan, Pascalis, & Johnson, 2002).

Regarding plasticity after maturation, there is also increasing evidence for cortical and cognitive plasticity extending beyond the developing brain to other periods of the lifespan. Many recent data show that the adult brain can also adaptively change its structural and functional organization in response to accumulated developmental history reflecting daily experiences and aging. For instance, Maguire et al. (2000) found that the brain region involved in storing spatial representation of the environment (i.e., posterior hippocampi) of adults who had extensive spatial navigation experience (i.e., taxi drivers who navigate in big cities) was significantly larger in comparison to age controls. As

for functional plasticity during aging, a series of recent neuroimaging data found evidence for reorganization of cortical functions in old age. In comparison to the more clearly lateralized cortical information processing in young adults, people in their 60s and beyond showed bilateralized (bihemispheric) activity during memory retrieval (e.g., Cabeza, 2002; Cabeza et al., 1997) and during both verbal and spatial working memory processing (e.g., Reuter-Lorenz et al., 2000). It has been suggested that these data might indicate that the aging brain could "recruit" cortical areas in both hemispheres to compensate for neurocognitive declines during aging. Regarding structural plasticity in old age, recently neuroscience's century-old dogma that there is no addition of new neurons in the adult mammalian brain has also been revised. There is now evidence that increased environmental complexity stimulates the growth of new hippocampal neurons (i.e., neurogenesis) in the adult brains of various species, such as birds, rats, and humans (see Gross, 2000, for a review). Data also indicate that physical exercise training that increases aerobic fitness reduces aging-related loss in gray and white matter density (Colcombe et al., 2003).

In summary, sociocultural influences could have effects on the brain's structural and functional organization through early experiential "tuning" of synaptic connections and functional circuitry. In addition, though less flexible than in the early part of development, there is still marked cortical plasticity throughout most of the adult lifespan, both in terms of structural and functional plasticity. This opens up possibilities for cultural and experiential influences to be intimately integrated into the individual's cumulative developmental history, reflecting lifelong adaptations both to ongoing life experiences couched in the respective sociocultural context and to lifespan developmental change in the efficacy and integrity of the brain itself.

EXAMPLES OF BIO-CULTURAL CO-CONSTRUCTION

Because the interdisciplinary research on biocultural co-construction of lifespan neurocognitive development is still in a very early developing stage, available studies are limited. Nevertheless, three sets of selective findings reviewed in this section demonstrate, particularly, the reciprocal influences of social con-

texts, culture-specific language environment, and expertise training.

Coevolution of Social Group Size, Language, and Brain

Focusing predominantly on the human phylogenetic scale, Dunbar (1993, 2003) showed that group size covaries with relative neocortical volume in nonhuman primates. This led to the proposal that the brain's encephalization is not driven by the cognitive demands of toolmaking, but by an intricate co-evolving process between the growth in brain size and the need to manage increasing social bonding complexity associated with larger social group size. More recent data comparing the complexity of social structure in New World and Old World monkeys, in part, also supported this proposal. D. A. Clark, Mitra, and Wang (2001) found that the neocortical volume of Old World monkeys, as well as some orders of New World monkeys with more complex social structure resembling that of Old World monkeys, is larger than that of New World monkeys with less complex social structure. Furthermore, based on a similar percentage of daily time (20%) spent for social grooming in primate and social interactions in modern human populations, Dunbar (1993) also argued that language evolved to be a more efficient way for humans to deal with the increased social complexity associated with the larger human group size in comparison to that of the primates. The use of language as a communication medium further requires humans to evolve and develop competency in understanding and inferring the intentions of others (i.e., theory of mind; Baron-Cohen, 1995). The subsequent effect on the level of individual ontogeny, in turn, was for language to become part of the socially inherited, species-specific cultural resources for different societies to support individuals' interactions with each other and with the environment. Indeed, the linguistic relativity theory (Saunders & van Brakel, 1997; Whorf, 1956) contends that human understanding of the world is, in part, constructed through language.

Brain encephalization is also correlated with the extended juvenile periods in primates and humans (Joffe, 1997). It has been suggested that this relation may also arise from selection pressures associated with complex social dynamics, because young individuals of species

with more complex social structure need more efficient communication skills to manage more intricate social interactions. The acquisition of sophisticated communication skills, in turn, may benefit from an extended juvenile period during which the individual not only learns elaborate means of communication but also develops more fully proficiency in interpreting the behavior and intention of other species members (Bjorklund & Pellegrini, 2000). The extended juvenile period in humans, in turn, allows an extended amount of time and opportunities for intergenerational social interactions, operating in conjunction with language and other cultural resources, to influence brain and cognitive development.

Co-Construction of Cultural Knowledge and Cognitive and Neural Plasticity

Language is perhaps the most ubiquitous, pragmatic daily skill that individuals of a given sociocultural group acquire through socialization. Literally, the daily contexts of *Homo sapiens*, are overlaid by the linguistic environments in which we are either at home (i.e., mother language context) or in which we find ourselves (e.g., foreign language contexts). The specific features of different languages contribute to fine differentiations between different linguistic environments. A language-specific linguistic environment affects the development of language processes through formal (e.g., phonology, orthography, and verb morphology) or social-interactive (e.g., parental speech) aspects of language. For instance, infants show better generalizations to phonetic variants around the prototypes contained in their native languages, a phenomenon known as the "perceptual magnet effect" (Kuhl, Williams, Lacerda, Stevens, & Lindblom, 1992). Culture-specific language differences may also influence parental speech and subsequently affect patterns of semantic and cognitive development. For instance, the English and Korean languages differ in their verb morphology, among other things. English has a highly analytic structure, with relative little reliance on morphological variations. Nouns are generally obligatory in English sentences, and it is rare to construct sentences consisting of only an inflected verb, without nouns or pronouns. English-speaking parents thus focus heavily on object naming in conversations with their children. In contrast, the Korean language has rich verb morphology,

with different verb endings marking important semantic distinctions. Thus Korean parental speech often consists of highly inflected verbs with few nouns. It has been suggested that differences in verb morphology between Korean and English may contribute to the developmental pattern of Korean children acquiring verbs that are relevant to the concepts of planning first, and nouns relevant for object categorization second, whereas the order of the developmental pattern is reversed in American children (Gopnik, Choi, & Baumberger, 1996).

Language acquisition at the behavioral level may have major implications for the functional architecture of the brain. Recent cognitive neuroscience findings indicate a dynamic shift in cortical organization over the course of language acquisition during childhood (see Neville et al., 1998, for a review). Similarly, the progressive developmental history of learning and using languages of different orthographical complexity throughout adult life leaves its trace at the cortical level. For instance, in comparison to the Italian language, English orthography is rather inconsistent, with complicated mappings of letters to sounds. Paulesu et al. (2000) recently found that Italian readers showed greater activation in the left superior temporal regions associated with phoneme processing, whereas English readers showed greater activations, particularly for nonwords, in the left posterior inferior temporal gyrus and anterior frontal gyrus, areas associated with word retrieval during both reading and naming tasks. These data suggest that acquiring the rather complex orthographical mapping of the English language impels English readers to invoke additional neurocognitive mechanisms involving word retrieval from semantic memory while reading.

Co-Construction of Person-Specific Expertise and Cognitive and Neural Plasticity

Throughout, it is emphasized that cognitive development across the lifespan has an ever increasingly strong component of individualization that likely cannot be entirely captured by individual differences in basic information-processing mechanisms and their neurobiological substrates. The case of individual differences in experiences and life histories reflecting socioculturally structured contextual influence can perhaps be best illustrated with respect to

occupational contexts. Different types of occupations engender, for instance, job-related stimulus and demand characteristics of varying complexity in individuals' daily job contexts and related experience-based outcomes. At the behavioral level, longitudinal studies have demonstrated reciprocal effects between the complexity of the occupational contexts and intellectual functioning in older adults (e.g., Schooler, Mulatu, & Oates, 1999; Schooler & Mulatu, 2004).

Another naturalistic setting for considering person-specific sociocultural influences on lifespan cognition is bilingualism (or multilingualism in general). As mentioned earlier, language is a representative aspect of general pragmatic knowledge that individuals of a given sociocultural group acquire. However, individuals may differ in their language expertise in terms of whether they need to master more than one language for their daily functioning. Child developmental and aging research have shown that the daily experience of processing two or more languages is associated with bilingual individuals' advantage in executive control functions that were measured by working memory or inhibition tasks (Bialystok, 2001; Bialystok, Craik, Klein, & Viswanathan, 2004).

Other than understanding the influences of sociocultural context on cognitive plasticity in natural settings, cognitive intervention studies reveal cognitive plasticity in individuals, even individuals in old age (see Kramer & Willis, 2002, for a review; Baltes & Lindenberger, 1988). Such research has primarily two goals. The first is to understand processes that underlie cognitive performance and its ontogeny. The second is to explore the range of what is possible in principle. In terms of memory plasticity in old age, memory training studies employing the testing-the-limit paradigm (an experimental paradigm that accesses individuals' current performance and maximum performance after extensive training) showed that older adults (from about 60 to 80 years) still displayed a fair level of cognitive plasticity and improved their associative memory by learning a culture-based mnemonic technique (i.e., the method of loci; Baltes & Kliegl, 1992). This technique is among the oldest mnemonic devices that was originated with the ancient Greeks around 500 B.C. When applying this mnemonic, the individuals learn to associate parts of the to-be-

remembered material with different locations in a familiar place, in the order that the materials need to be recalled later. This method helps to improve memory for associations between memory events by linking them with the order of locations in the already familiar environment (see Bower, 1970, for classical review).

Aside from the demonstration of performance enhancement by acquiring special skills, these studies exemplify how training research using the testing-the-limit paradigm explores constraints on the zone (range) of potential development (Baltes, 1997). Thus, not unlike contemporary work in childhood, the focus is on maximum limits. Despite the continued plasticity in older ages, it could be shown that the cognitive plasticity of older individuals in the fourth age (i.e., 80 years and older) is markedly reduced in comparison to young adults (Singer et al., 2003). Extending the testing-the-limit memory training across the lifespan, the evidence shows that young children around 10 years of age have greater developmental reserve plasticity than older adults around 70 years of age (Brehmer et al., 2004).

In a way, expertise acquisition can be considered as long-term “testing-the-limit” type of training implemented in the natural settings of individuals’ daily experiences. Expert performance is the result of intense practice extended for at least a minimum of 10 years for most domains of skills (Ericsson, Krampe, & Tesch-Römer, 1993). In the domain of music expertise, empirical evidence suggest that the long-term extended daily practice of older expert pianists helps to maintain their elite performance, in spite of age-related decline in basic cognitive processes (Krampe & Ericsson, 1996). There is also evidence that long-term acquisition of expertise leads to experience-induced cortical functional reorganization, in addition to behavioral changes. For instance, Elbert, Pantev, Wienbruch, Rockstroh, and Taub (1995) found that cortical representations of the fingers of the left hands of string players were larger than those of the right hand holding the bow, and this was particularly true for individuals who started playing the instrument early in life. Outside the domain of music, Maguire et al. (2000) found that given their extensive navigation experience, London taxi drivers’ posterior hippocampi, a region of the brain involved in storing spatial representation of the environment, were significantly larger in

comparison to same-age individuals who did not have as much navigation experience. Furthermore, when comparing drivers, the number of years spent as a taxi driver correlated positively with hippocampal volume. These data indicate that the adult brain still possesses functional plasticity, allowing the posterior hippocampus to expand to accommodate elaboration of environmental spatial representation in individuals who rely heavily on their navigation skills and have achieved a high level of navigation expertise in a particular environment.

CONCLUDING REMARKS

Admittedly, findings regarding sociocultural influences on lifespan neurocognitive development are still very limited and leave many gaps between the different levels of analyses at the current stage. Nevertheless, the fact that there are emerging co-constructive views and empirical evidence of developmental plasticity at various levels, as reviewed in this chapter, indicates that at least the possibilities for bridging these gaps are gradually on the rise.

Given neural plasticity that responds to lifespan developmental changes in the integrity of the brain itself, as well as lifelong adaptations to ongoing life experiences couched in the individual’s own respective sociocultural context, future research needs to focus less on the commonly used localization approach to study neurocognitive processes, mainly by analyzing regional activation differences as a function of task conditions. Instead, lifespan changes and individual differences in brain-behavior mapping need to be considered more explicitly (Li & Lindenberger, 2002). For instance, instead of assuming that cortical regions and circuitry associated with particular functionalities in normal adult are very similar, if not identical, to those in developing children or old adults, lifespan changes in brain-behavior mapping need to be investigated and taken into account (e.g., Cabeza, 2002; Grady, McIntosh, & Craik, 2003; Karmiloff-Smith, 1998; Reuter-Lorenz, 2002; Schlaggar et al., 2002).

The biocultural co-constructive and adaptive nature of cognitive development cautions against an immediate interpretation of age differences in cognitive operations as solely driven by the growth and decline of basic

information-processing mechanisms and their associated neurobiological mechanisms. The biocultural co-construction framework highlights lifespan variations in the relative contributions of biology and culture to cognitive functioning. In early cognitive development, idiosyncratic person-specific experiences tend to play a lesser role relative to contributions of species-typical neurobiological and age-normative sociocultural factors. In subsequent phases of lifespan development, however, life-history-specific influences may be more significant for understanding adult cognitive development and aging. In old age, because of the pervasiveness of biological decline, processes of greater generality are likely to reenter the system as powerful regulating forces of the developmental trajectories. Evidence reviewed in this chapter provides initial support for these propositions. Further empirical verifications will require combined age- and culture-comparative, cross-level designs that examine basic cognitive and neuronal processes in well-controlled laboratory settings, as well as studies of cognition in everyday functioning using ecologically valid tasks that reflect sociocultural specificities (e.g., Gopnik et al., 1996; Kelly, Miller, Fang, & Fang, 1999; Kitayama et al., 2003; Nisbett et al., 2001; Park, Nisbett, & Hedden, 1999; Paulesu et al., 2000; Snibbe, Kitayama, Markus, & Suzuki, 2003).

In conclusion, the existing empirical evidence of developmental plasticity at different levels presents a warning against the “pure reductionist approach” to the genetic and neuronal bases of mind and behavior that ignores the influences from cultural, experiential, and cumulative developmental contexts. The reason is clear: Genetic activities and neural mechanisms themselves possess remarkable plasticity awaiting sociocultural contexts to exert reciprocal influences on them and to be the “coauthors” of mind and behavior. People are more than mere biological organisms; human mind and behavior need to be understood in the proper context within a brain, in a body that lives in an eventful world abounding with objects and people. Indeed, the brain offers the necessary biophysical reality for individual cognition and action; it alone, however, is not sufficient to engender the mind or behavior. On the mind–brain continuum, the individual mind is the expression emerging from the per-

sonalized brain (Greenfield, 2000; Llinas & Churchland, 1996). The very processes for personalizing the biological faculty of the mind take place throughout lifespan development in environmental and sociocultural contexts, which entail intimate dynamical exchanges between nature and nurture, biology and culture.

PART V

COGNITION

CHAPTER 22

Intelligence and Culture

ROBERT J. STERNBERG

The study of culture and intelligence is based in part on the notion that behavior that in one cultural context is smart may be stupid in another cultural context (Cole, Gay, Glick, & Sharp, 1971; Sternberg, 2004a). Stating one's political views honestly and openly, for example, may win one the top political job, such as the presidency, in one culture, and the gallows in another.

One reason to study culture and intelligence is because they are so inextricably interlinked. Indeed, Tomasello (2001) has argued that culture is what, in large part, separates human from animal intelligence. Humans have evolved as they have, he believes, in part because of their cultural adaptations, which in turn develop even in infancy from about 9 months onward, from their ability to understand others as intentional agents.

The conceptualization, assessment, and development of intelligence cannot be fully or even meaningfully understood outside their cultural context. Work that seeks to study intelligence acontextually may impose an, often Western, investigator's view of the world on the rest of the world, frequently attempting to show that individuals who are more similar to the investigator are smarter than individuals who are less similar. Here, the term "Western" refers primarily to middle- to upper-middle-

class North Americans and Western Europeans, so the term is used in a specific way, and not to refer to anyone who happens to live in the "West." For example, a test of intelligence developed and validated in one culture may or may not be equally valid, or even be valid at all, in another culture.

This chapter is divided into five parts. First, I define the main concepts of the chapter, *culture* and *intelligence*. Second, models of the relationship between culture and intelligence are specified. Third, the text introduces the chapter's ideas, including a description of some studies investigating various issues relating culture to intelligence. Fourth, I discuss cultural studies relevant to these ideas. Fifth, I consider whether "culture-fair" testing is possible, and finally, draw some conclusions.

WHAT IS CULTURE AND WHAT IS INTELLIGENCE?

Defining Culture

Because the topic of this chapter is culture and intelligence, it is necessary to define these constructs.

There have been many definitions of *culture* (e.g., Brislin, Lonner, & Thorndike, 1973; Kroeber & Kluckhohn, 1952), which is defined here as "the set of attitudes, values, beliefs and

behaviors shared by a group of people, communicated from one generation to the next via language or some other means of communication (Barnouw, 1985)” (Matsumoto, 1994, p. 4). The term *culture* can be used in many ways and has a long history (Benedict, 1946; Boas, 1911; Mead, 1928; see Matsumoto, 1996). Berry, Poortinga, Segall, and Dasen (1992) described six uses of the term: descriptively to characterize a culture, historically to describe the traditions of a group, normatively to express rules and norms of a group, psychologically to emphasize how a group learns and solves problems, structurally to emphasize the organizational elements of a culture, and genetically to describe cultural origins.

Defining Intelligence

How is intelligence defined? Some psychologists, such as Edwin Boring (1923), have been content to define intelligence as whatever it is that tests of intelligence measure. This definition, unfortunately, is circular, because, according to it, the nature of intelligence determines what is tested, but what is tested must necessarily be determined by the nature of intelligence. Moreover, what different tests of intelligence test is not always the same thing. Different tests measure somewhat different constructs (Daniel, 1997, 2000; Embretson & McCollam, 2000; Kaufman, 2000; Kaufman & Lichtenberger, 1998), so it is not feasible to define intelligence by what tests test, as though they all measure the same thing.

Moreover, if intelligence were to turn out to be not quite the same thing from one culture to another, the definition would become totally vacuous, meaning as many different things as there are cultures. Tests, of course, can be translated. But what is to be translated? Obviously, a test of English vocabulary would not work well in Dholuo-speaking rural Kenya, such as in the town of Busia. So the words would, at least, need to be translated. But are the translated words that would be optimal on a test in English the same ones that would be optimal on a test in Dholuo? Are there even exact translations, given that the roots of the two languages are so different? Perhaps not. But then, is vocabulary for low-frequency words itself of equal importance to village residents in rural Busia, Kenya, and to residents of, say, Cambridge, Massachusetts? The residents of the town will probably never use any of those

complex words in their lives, and they may not even exist in their language. But to survive, those residents need to know how to farm under very difficult conditions, and a test of farming knowledge would be quite appropriate to them as a measure of their adaptive skills. Most of the readers of this chapter would have difficulty answering the farming vocabulary questions that would be relevant to their lives, even in translation. Boring's definition simply does not hold up well under close cultural scrutiny.

Historically, there are many different definitions of intelligence (“Intelligence and Its Measurement,” 1921; Sternberg, 2000; Sternberg & Detterman, 1986). Over time, a consensus definition has tended to emphasize two important skills: adaptation to the environment and the ability to think and learn. In more recent times, a third component has been added to the definition, namely, understanding oneself and one's own skills, often referred to as *metacognition*. Broadly speaking, metacognition also includes theory of mind in general, or one's understanding of how other people's minds work as well. So a consensus of traditional definitions of *intelligence* is “the ability to adapt to the environment, to think and learn, and to understand oneself and others.”

THEORIES OF INTELLIGENCE

Theories of intelligence are of two kinds: Explicit theories are proposed by investigators, and tested through and often suggested by empirical studies; implicit theories are folktheories—theories that people have in their heads.

Explicit theories and implicit theories are related in various ways. First, implicit theories of professionals serve as the bases for their explicit theories. Unfortunately, professionals, often unaware of this fact, so may not realize the extent to which their explicit theories are shaped and also limited by their implicit ones. Second, both kinds of theories are used in assessing intelligence. By far, more judgments are based on implicit theories—for example, judging candidates in job interviews, assessing acquaintances in casual encounters, evaluating partners in dating, evaluating potential business partners, and so forth. Third, laypeople and professionals alike tend to believe that implicit theories are somehow less “scientific”

than explicit theories, although intelligence is in part a social construction, so it is not clear that implicit theories are less scientific. The science is in uncovering what they are. Finally, explicit theories are typically presented as being cross-culturally relevant, whereas such a claim is typically not made for implicit theories. But often tests of explicit theories across cultures assume rather than actually validate theories in the different cultures.

It may be that if Western norms and schooling spread across the world, then the explicit theories developed in the West will become more relevant around the world. But the trend toward Westernization is by no means the only trend in the world today. In much of the world, individuals are rebelling against what they see as an unwarranted and unwelcome encroachment of Westerners and Western values. So it is not clear just where things ultimately will go.

Explicit Theories of Intelligence

Conventional Psychometric Theories

Today, the most widely accepted traditional theories of intelligence are hierarchical ones. They build on the work of Charles Spearman (1904/1927), who proposed a factor of general intelligence (*g*), and of Louis Thurstone (1938), who proposed multiple factors of intelligence (verbal comprehension, number, verbal fluency, memory, perceptual speed, reasoning, spatial visualization). One such model, developed by Raymond Cattell (1971), proposed that general intelligence comprises two major subfactors: fluid ability (speed and accuracy of abstract reasoning, especially for novel problems) and crystallized ability (accumulated knowledge and vocabulary). Subsumed within these two major subfactors are other, more specific factors. A similar view was proposed by Philip E. Vernon (1969, 1971), who made a general division between practical–mechanical and verbal–educational abilities.

More recently, John B. Carroll (1993) proposed a hierarchical model of intelligence, based on his analysis of more than 460 data sets obtained between 1927 and 1987. His analysis encompasses more than 130,000 people from diverse walks of life and even countries of origin (although non-English-speaking countries are poorly represented among his data sets). The model Carroll proposed, based on his monumental undertaking, is a hierarchy

comprising three strata: Stratum I includes many narrow, specific abilities (e.g., spelling ability, speed of reasoning); Stratum II includes various broad abilities (e.g., fluid intelligence, crystallized intelligence); and Stratum III is just a single general intelligence, much like Spearman's *g*. Of these strata, the most interesting is Stratum II, which is neither too narrow nor too all-encompassing.

In addition to fluid intelligence and crystallized intelligence, Carroll includes in Stratum II learning and memory processes, visual perception, auditory perception, facile production of ideas (similar to verbal fluency), and speed (which includes both sheer speed of response and speed of accurate responding). Although Carroll does not break new ground, in that many of the abilities in his model have been mentioned in other theories, he does masterfully integrate a large and diverse factor-analytic literature, thereby giving great authority to his model. Whereas the factor-analytic approach has tended to emphasize the structures of intelligence, the information-processing approach has tended to emphasize the operations of intelligence.

Of course, there are many alternative theories of intelligence as well (Ceci, 1996; Spearman, 1904/1927; Thurstone, 1938), many of which are reviewed in Sternberg (1990, 2000). Consider just two of these.

Systems Theories

In recent times, some scholars have sought broader definitions of intelligence than was customary in the past. For example, Gardner (1983) does not believe in a single intelligence, but rather, in multiple intelligences. He has defined "multiple intelligences" as emanating from one's ability to work in multiple symbol systems, in particular, linguistic, logical–mathematical, spatial, musical, bodily–kinesthetic, naturalist, interpersonal, and intrapersonal. He has also speculated on the existence of an existential intelligence, which deals with broader questions of existence.

Each intelligence is a separate system of functioning. Nevertheless, these systems can interact to produce intelligent performance. For example, novelists rely heavily on linguistic intelligence but might use logical–mathematical intelligence in plotting story lines or checking for logical inconsistencies. Measuring intelligences separately may produce a

profile of skills that is broader than would be obtained from, say, measuring verbal and mathematical abilities alone.

To identify particular intelligences, Gardner (1983) used converging operations, gathering evidence from multiple sources and types of data. The evidence includes (but is not limited to) the distinctive effects of localized brain damage on specific kinds of intelligences, distinctive patterns of development in each kind of intelligence across the lifespan, exceptional individuals (from both ends of the spectrum), and evolutionary history.

Gardner's theory (1983) is particularly relevant to those with cultural interests, because it puts into the realm of intelligence skills that traditional theories and cross-cultural investigations might neglect. For example, Romani (Gypsy) culture puts a large emphasis on the development of both musical and interpersonal skills. It also puts a heavy emphasis on oral storytelling skills (Fraser, 1995; Hancock, 1999). A traditional theory of intelligence would hold these skills as being outside the realm of intelligence. Thus, an illiterate Romani person might have trouble being classified as intelligent by traditional standards, because of the heavy emphasis in most tests of intelligence on understanding written verbal materials. But according to Gardner's theory, musical, interpersonal, and oral storytelling skills would all be relevant to the assessment of Romani intelligence, and potentially, anyone else's as well. Profiles comparing different peoples might therefore be quite different in Gardner's theory than in a traditional one. In a traditional theory, the development of such skills would be seen as outside the domain of intelligence. In essence, they simply would not "count."

Another theory arguing for a broader definition of intelligence is the theory of successful intelligence (see Sternberg, 1985, 1997, 1999b, for more details), which proposes its own definition of intelligence. The term "successful" intelligence is used to underscore the importance of understanding intelligence as a predictor of not only academic performance, in the tradition of Binet and Simon (1916), but also of success in life. This theory defines "successful" intelligence as the skills and knowledge needed for success in life, according to one's own definition of success, within one's sociocultural context. One acquires and utilizes these skills

and this knowledge by capitalizing on strengths, by correcting or compensating for weaknesses, and by adapting to, shaping, or selecting environments through a balance of analytical, creative, and practical abilities.

In solving problems and making decisions, metacomponents, or higher order processes, determine what one is to do. Performance components actually do the work. And knowledge-acquisition components enable one to learn how to do it in the first place. Analytical intelligence results when components are applied to fairly abstract but familiar kinds of problems. Creative intelligence results when the components are applied to relatively novel tasks and situations. Practical intelligence results when the components are applied to experience for purposes of adaptation, shaping, and selection (e.g., Baltes, Dittmann-Kohli, & Dixon, 1984; Scribner, 1984, 1986; Sternberg et al., 2000).

Implicit Theories of Intelligence

Intelligence may be conceived in different ways in different cultures (see reviews in Serpell, 2000; and Sternberg & Kaufman, 1998). Such differences are important, because cultures evaluate their members, as well as members of others cultures, in terms of their own conceptions of intelligence.

The differences between Western and Eastern implicit theories of intelligence in many ways reflect the differences noted between Western and Eastern ways of thinking. In these terms, however, African conceptions would fit more into Eastern rather than Western views. For example, Markus and Kitayama (1991) have noted the greater tendency of Westerners to think in individualistic terms and of Easterners to think in collectivistic terms, and these differences are reflected in some ways in the implicit theories to be described. Moreover, Nisbett's (2003) characterization of differences between Western and Eastern cultures also apply, with Western views tending to be linear, context-independent, and less situated, and Eastern views tending to be more situated, nonlinear and dialectical, and context-dependent. If one accepts that implicit theories may drive people to socialize intelligence in different ways in different cultures, one may be inclined to test intelligence in different ways in different cultures, because parents may socialize the in-

telligence of children in different ways in different cultures (Sternberg & Suben, 1986).

In some cases, Western notions about intelligence are not shared by other cultures. For example, at the mental level, Western emphasis on speed of mental processing (Sternberg, Conway, Ketrone, & Bernstein, 1981) is not shared in many cultures. Other cultures may even be suspicious of the quality of work that is done very quickly. Indeed, other cultures emphasize depth rather than speed of processing. They are not alone: Some prominent Western theorists have pointed out the importance of depth of processing for full command of material (e.g., Craik & Lockhart, 1972). Western tests often are narrowly constructed to reflect Western notions of the importance of time rather than any universal notion of its importance.

Often, Western investigators act as though their theories of intelligence—explicit or implicit—are not just proposals, but facts. For example, comparisons of intelligence across groups, as illustrated by Herrnstein and Murray (1994), assume that Western tests measure the same skills for all groups being compared and, moreover, are equally valid for all groups being compared. The result is that, typically, those groups that invent tests tend to do the best on them, then to feel intellectually superior to other groups. In this instance, Western groups might not do so well on tests created to measure adaptation in other environments. For example, their knowledge of natural herbal medications used to combat parasitic infections might be nil, but they would not sense any problem, because items measuring this knowledge would not appear on *their* tests.

In a study of implicit theories, Chen and Chen (1988) varied only the language. They explicitly compared the concepts of intelligence of Chinese graduates from Chinese-language versus English-language schools in Hong Kong. They found that both groups considered non-verbal reasoning skills as the most relevant skill for measuring intelligence. Verbal reasoning and social skills came next, and then numerical skill. Memory was seen as least important. The Chinese-language-schooled group, however, tended to rate verbal skills as less important than did the English-language-schooled group. Moreover, in an earlier study, Chen, Braithwaite, and Huang (1982) found that

Chinese students viewed memory for facts as important for intelligence, whereas Australian students viewed these skills as of only trivial importance.

Das (1994), also reviewing Eastern notions of intelligence, has suggested that in Buddhist and Hindu philosophies, intelligence not only involves waking up, noticing, recognizing, understanding, and comprehending, but also includes things such as determination, mental effort, and even feelings and opinions, in addition to more intellectual elements.

Differences between cultures in conceptions of intelligence have been recognized for some time. Gill and Keats (1980) noted that Australian university students value academic skills and the ability to adapt to new events as critical to intelligence, whereas Malay students value practical skills, as well as speed and creativity. Dasen (1984) found that Malay students emphasize both social and cognitive attributes in their conceptions of intelligence.

The differences between East and West may be due to differences in the kinds of skills valued by the two kinds of cultures (Srivastava & Misra, 1996). Western cultures and their schools emphasize what might be called “technological intelligence” (Mundy-Castle, 1974), so things such as artificial intelligence and so-called smart bombs are viewed, in some sense, as intelligent, or smart. African cultures place more emphasis on “social intelligence” (Mundy-Castle, 1974).

Western schooling also emphasizes other things (Srivastava & Misra, 1996), such as generalization, or going beyond the information given (Connolly & Bruner, 1974; Goodnow, 1976), speed (Sternberg, 1985), minimal moves to a solution (Newell & Simon, 1972), and creative thinking (Goodnow, 1976). Moreover, silence is interpreted as a lack of knowledge (Irvine, 1978). In contrast, the Wolof tribe in Africa views people of higher social class and distinction as speaking less (Irvine, 1978). This difference between the Wolof and Western notions suggests the usefulness of looking at African notions of intelligence as a possible contrast to U.S. notions.

Similar emphasis on social aspects of intelligence has been found as well among two other African groups—the Songhay of Mali and the Samia of Kenya (Putnam & Kilbride, 1980). The Yoruba, another African tribe, emphasize the importance of depth—of listening rather

than just talking—to intelligence, and of being able to see all aspects of an issue and to place the issue in its proper overall context (Durojaiye, 1993).

Emphasis on the social aspects of intelligence is not limited to African cultures. Notions of intelligence in many Asian cultures also emphasize the social aspect of intelligence more than does the conventional Western or IQ-based notion (Azuma & Kashiwagi, 1987; Lutz, 1985; Poole, 1985; White, 1985).

In China, the Confucian perspective emphasizes the characteristic of benevolence and of doing what is right (Shi, 2004; Yang, 2001; Yang & Sternberg, 1997a). As in the Western notion, the intelligent person spends a great deal of effort in learning, enjoys learning, and persists in lifelong learning with a great deal of enthusiasm. The Taoist tradition, in contrast, emphasizes the importance of humility, freedom from conventional standards of judgment, and full knowledge of oneself, as well as of external conditions.

China is believed to be the first nation to employ widely tests of intelligence (Shi, 2004). Tests were used in ancient China for employment purposes. The tangram, which requires an individual to construct shapes, was first developed in the Song dynasty (Lin, 1980). Even young children were tested for their developmental skills, for example, by placing objects where they belong (Yan, 2001).

The difference between Eastern and Western conceptions of intelligence may persist even in the present day. Yang and Sternberg (1997b) studied contemporary Taiwanese Chinese conceptions of intelligence and found five factors underlying these conceptions: (1) a general cognitive factor, much like the *g* factor in conventional Western tests; (2) interpersonal intelligence (i.e., social competence); (3) intrapersonal intelligence; (4) intellectual self-assertion; and (5) intellectual self-effacement. In a related study, but with different results, Chen (1994) found three factors underlying Chinese conceptualizations of intelligence: (1) nonverbal reasoning ability, (2) verbal reasoning ability, and (3) rote memory. The difference may be due to different subpopulations of Chinese, to differences in methodology, or to differences in when the studies were done.

The factors uncovered in Taiwan differ substantially from those identified in U.S. people's conceptions of intelligence by Sternberg et al.

(1981): (1) practical problem solving, (2) verbal ability, and (3) social competence. In both cases, however, people's implicit theories of intelligence seem to go quite far beyond what conventional psychometric intelligence tests measure. Of course, comparing the Chen (1994) study to the Sternberg et al. (1981) study simultaneously varies both language and culture.

Studies in Africa in fact provide yet another window on the substantial differences in conceptions of intelligence across cultures. Ruzgis and Grigorenko (1994) argued that, in Africa, conceptions of intelligence revolve largely around skills that help to facilitate and maintain harmonious and stable intergroup relations; intragroup relations are probably equally important and at times more important. For example, Serpell (1974, 1996) found that Chewa adults in Zambia emphasize social responsibilities, cooperativeness, and obedience as being important to intelligence; intelligent children are expected to be respectful of adults. Kenyan parents also emphasize responsible participation in family and social life as being important aspects of intelligence (Super & Harkness, 1982, 1986, 1993). In Zimbabwe, one word for intelligence, *ngware*, actually means to be prudent and cautious, particularly in social relationships. Among the Baoule, service to the family and community, and politeness toward and respect for elders are seen as key to intelligence (Dasen, 1984). In Zimbabwe, conceptions of intelligence are also represented by *njere* (in the Shona language) and *ukaliphile* (in the Ndebele language; Mpofu, 2004). The terms refer to behavior that is deliberate, socially responsible, positive, public-spirited, and altruistic (Chimhundu, 2001; Hadebe, 2001; Irvine, 1988; Mpofu, 1993, 2004). They also mean "wise," indicating that, as in Taiwanese Chinese culture (Yang & Sternberg, 1997a, 1997b), wisdom and intelligence are seen as closely related. Behavior is considered intelligent to the extent it benefits the community as a whole (Mpofu, 2004).

In India, words related to intelligence include *buddhi* (Sanskrit), which refers to awareness or consciousness (Baral & Das, 2004). Intelligence has been treated as a state, a process, or an entity in Indian philosophical literature (Srivastava & Misra, 2000). Das (1994) has referred to intelligence in Indian philosophy as pertaining to waking up, noticing, understanding, and comprehending.

In Latin America, implicit theories of teachers tend to emphasize academic skills as the main basis of intelligence (Kaplan, 1997). For example, in Argentina, Kaplan found that teachers emphasized the following as important to intelligence: good discipline, interest in learning, learning and thinking ability, and also coming from a stable home. Many teachers in this study also believed in the concept of a “bad head,” that is, a head not suited to studying.

It is difficult to separate linguistic and conceptual differences in cross-cultural notions of intelligence. Converging operations can be used to achieve some separation; that is, different and diverse empirical operations can be employed to ascertain notions of intelligence. So one may ask in one study that people identify aspects of competence; in another, that they identify competent people; and in yet another study, that they characterize the meaning of “intelligence,” and so forth.

The emphasis on the social aspects of intelligence is not limited to African cultures. Notions of intelligence in many Asian cultures also emphasize the social aspect of intelligence more than does the conventional Western or IQ-based notion (Azuma & Kashiwagi, 1987; Lutz, 1985; Poole, 1985; White, 1985).

It should be noted that neither African nor Asian notions emphasize exclusively social notions of intelligence. These conceptions of intelligence emphasize social skills much more than do conventional U.S. conceptions of intelligence, at the same time that they recognize the importance of cognitive aspects of intelligence. In a study of Kenyan conceptions of intelligence, Grigorenko et al. (2001) found that there are four distinct terms constituting conceptions of intelligence among rural Kenyans—*rieko* (knowledge and skills), *luoro* (respect), *winjo* (comprehension of how to handle real-life problems), *paro* (initiative)—with only the first directly referring to knowledge-based skills (including but not limited to academic endeavors).

Intelligence is viewed as being of great importance in many Western and some other cultures. This emphasis is not shared throughout the world. In Japan, for example, people rarely refer to an individual’s level of intelligence at all (Sato, Namiki, Ando, & Hatano, 2004). Rather, there is much more emphasis on a person’s motivation and diligence. Success is viewed as much more dependent on motivation than on intelligence (Sato et al., 2004). When

participants are given a task followed by success or failure feedback, Japanese students are more likely to attribute success to effort, good luck, or various situational factors, whereas American students are more likely to attribute success to their ability. In contrast, where as Japanese students are likely to attribute failure to lack of effort, the Americans attribute it to lack of ability (Miyamoto, 1985). Nevertheless, Japanese people do have a conception of intelligence. Factors emerging from a study of implicit theories were active social competence, processing efficiency, and receptive social competence (Azuma & Kashiwagi, 1987). None of the factors were considered to be innate.

It is important to realize, again, that there is no single overall U.S. conception of intelligence. Indeed, Okagaki and Sternberg (1993) found that different ethnic groups in San Jose, California, had rather different conceptions of what it means to be intelligent. For example, Latino parents of schoolchildren tended to emphasize the importance of social competence skills in their conceptions of intelligence, whereas Asian parents tended to emphasize rather heavily the importance of cognitive skills. Anglo parents also placed more emphasis on cognitive skills. Teachers, representing the dominant culture, emphasized more cognitive than social competence skills. The rank order of children of various groups’ performance (including subgroups within the Latino and Asian groups) could be perfectly predicted by the extent to which their parents shared teachers’ conceptions of intelligence. In other words, teachers tended to reward those children who were socialized into a view of intelligence that happened to correspond to their own.

Although researchers mostly emphasize lay implicit theories of intelligence in cultural studies, it is important to realize that expert implicit theories also differ. For example, Continental European thinking about intelligence, especially in French-speaking countries, was very heavily influenced by Piaget in the latter half of the 20th century, and this influence continues to be felt today (Lautrey & de Ribaupierre, 2004). Russian thinking was very heavily influenced by Vygotsky and Luria (Grigorenko, 2004). English thinking was very heavily influenced by Spearman (Deary & Smith, 2004), and North American thinking, by both Thurstone and Spearman (Sternberg, 2004c). Indian thinking was very heavily influenced by Eastern philosophy (Baral & Das, 2004).

MODELS OF THE RELATIONSHIP OF CULTURE TO INTELLIGENCE

Consider the four basic models of the relationship of culture to intelligence (Sternberg, 2004a; see also Sternberg, 1988, 1990) shown in Figure 22.1.

The models presented here differ in two key respects: whether there are cross-cultural differences in the nature of the mental processes and representations involved in adaptation that constitute intelligence, and whether there are differences in the instruments needed to measure intelligence (beyond simple translation or adaptation) as a result of cultural differences in the content required for adaptation.

In Model I, the nature of intelligence is the same across cultures, as are the tests used to measure intelligence. The theoretical positions of Jensen (1982, 1998) and Eysenck (1986) represent Model I types of positions. The argument is that the nature of intelligence is precisely the same cross-culturally, and that this nature can be assessed identically (using appropriate translations of text, where necessary) without regard to culture. For example, Jensen (1998) believes that general intelligence, or *g* (Spearman, 1927), is the same across time and place. What varies across time and place are its levels.

Model I is what is sometimes referred to as an “etic” approach to intelligence. One devises a measure or set of measures of a construct, then uses the measures in various cultures, sometimes doing minor adaptations to fit the measures to the culture (Carlstedt, Gustafsson, & Hautamäki, 2004; Deary & Smith, 2004; Demetriou & Papadopolous, 2004; Fernández-Ballesteros & Colom, 2004; Gulgoz & Kağitçibaşı, 2004; Rosas, 2004; Stankov, 2004; see, in general, essays in Sternberg, 2004b).

Model II represents a difference in the nature of intelligence but no difference in the instruments used to measure it. The measures used to assess intelligence are the same across cultures, but the outcomes obtained from using those measures are structurally different as a function of the culture being investigated. This approach is close to that taken by Nisbett (2003), who found that the same tests given in different cultures suggested that, across cultures, people think about problems in different ways.

In Model III, the dimensions of intelligence are the same, but the instruments of measurement are not. According to this view, measurement processes for a given attribute must be emic, that is, derived from within the context of the culture being studied rather than from outside it. This is not to say that the same instruments cannot be used across cultures, but when they are, the psychological meanings to be assigned to the scores will differ from one culture to another. This is the position taken in this chapter and in some earlier work (e.g., Sternberg, 1990).

According to this position, the components of intelligence and the mental representations on which they act are universal; that is, they are required for mental functioning in all cultures. For example, people in all cultures need to execute executive processes: (1) Recognize the existence of problems, (2) define what the problems are, (3) mentally represent the problems, (4) formulate one or more strategies for solving the problems, (5) allocate resources to solving the problems, (6) monitor solution of the problems, and (7) evaluate problem solving after it is done. What varies across cultures are the mental contents (i.e., types and items of knowledge) to which processes such as these are applied, and the judgments as to what are considered “intelligent” applications of the processes to these contents (Sternberg, 1997).

		Dimensions of Intelligence	
		Same	Different
Tests of Intelligence	Same	Model I	Model II
	Different	Model III	Model IV

FIGURE 22.1. Models of the relationship of culture to intelligence.

Thus, a wholly relativistic view of intelligence and culture would be inadequate. Some things are constant across cultures (mental representations and processes), whereas others are not (the contents to which they are applied and how their application is judged). Tests must be modified if they are to measure the same basic processes as they apply from one culture to another.

As a result, one can translate a particular test of intelligence, but there is no guarantee it will measure the same thing in one culture as in another. For example, a test that is highly novel in one culture or subculture may be quite familiar in the next. Even if the components of information processing are the same, the experiential novelty to which they are applied may be different. Moreover, the extent to which the given task is practically relevant to adaptation, shaping, and selection may differ. Hence, the components may be universal, but not necessarily the relative novelty or adaptive practicality of the components as applied to particular contents.

In Model IV, both the instruments and the ensuing dimensions of intelligence are different as a function of the culture under investigation. This position embraces the radical cultural relativist position (Berry, 1974) that intelligence can be understood and measured only as an indigenous construct within a given cultural context. It also embraces the position of Sarason and Doris (1979), who view intelligence largely as a cultural invention. In other words, nothing about intelligence is necessarily common across cultures.

Berry and Irvine (1986) have proposed four nested levels of the cultural context (in which intelligence and other hypothetical constructs reside). The broadest, ecological level, comprises the permanent or almost permanent characteristics that provide the backdrop for human action. The experiential context refers to the pattern of recurrent experiences within the ecological context that provides a basis for learning and development. The performance context comprises the limited set of environmental circumstances that account for particular behaviors at specific points in space and time. The narrowest, experimental context, comprises the environmental characteristics manipulated by psychologists and others to elicit particular responses or test scores.

STUDIES OF INTELLIGENCE IN ITS CULTURAL CONTEXTS

The previous discussion suggests that intelligence, understood wholly outside its cultural context, is a mythological construct. Some aspects of intelligence transcend cultures, namely, the mental processes underlying intelligence and the mental representations upon which they act. But these operations play themselves out in performance differently from one culture to another. As soon as one assesses performance, then, one is assessing mental processes and representations in a cultural context (Model III).

Most psychological research is done within a single culture. But single-cultural studies whose results are implicitly or even explicitly generalized across cultures potentially deprive the field in several ways. In particular, they may (1) introduce limited definitions of psychological phenomena and problems, (2) engender risks of unwarranted assumptions about the phenomena under investigation, (3) raise questions about cultural generalizability of findings, (4) engender risks of cultural imperialism, and (5) represent lost opportunities to collaborate and develop psychology around the world.

Many research programs demonstrate the potential hazards of single-culture research. For example, Greenfield (1997) found that it means a different thing to take a test among Mayan children than it does among most children in the United States. The Mayan expectation is that collaboration is permissible, and that it is rather unnatural *not* to collaborate. Clearly, only Model III or Model IV would apply if one accepted this difference as one that should be reflected in testing. Such a finding is consistent with the work of Markus and Kitayama (1991), suggesting different cultural constructions of the self in individualistic versus collectivistic cultures. Indeed, Nisbett (2003) has found that some cultures, especially Asian ones, tend to be more dialectical in their thinking, whereas European and North American cultures tend to be more linear. And individuals in different cultures may construct concepts in quite different ways, rendering results of concept formation or identification studies in a single culture suspect (Atran, 1999; Coley, Medin, Proffitt, Lynch, & Atran, 1999; Medin & Atran, 1999). Thus, groups may think about what appears superficially to be the same

phenomenon—whether a concept or the taking of a test—differently. What appear to be differences in *g* may in fact be differences in cultural properties (Helms-Lorenz, Van de Vijver, & Poortinga, 2003). Helms-Lorenz et al. have argued that measured differences in intellectual performance may result from differences in cultural complexity, but complexity of a culture is extremely hard to define, and what appears to be simple or complex from the point of view of one culture may appear different from the point of view of another.

Many investigators have realized the importance of cultural context for the psychology of intelligence and cognition. These realizations have taken diverse forms. Indeed, Berry (1974) reviewed concepts of intelligence across a wide variety of cultural contexts, showing major differences across cultures.

Cole (1998) and Shweder (1991, 2002) have helped define cultural psychology as a field, distinguishing it from cross-cultural psychology (e.g., Irvine, 1979; Irvine & Berry, 1983; Marsella, Tharp, & Ciborowski, 1979), which they believe tends to be somewhat less sensitive to differences among cultures. The studies described in this chapter represent both approaches, although our own studies are generally more in the “cultural” rather than “cross-cultural” tradition. Cole’s overview of the field builds on his earlier work (Cole et al., 1971; Cole & Means, 1981; Cole & Scribner, 1974; Laboratory of Comparative Human Cognition, 1982), which showed how cognitive performance among populations, such as the Kpelle in Africa, can be both qualitatively and quantitatively different from that of the North Americans, who typically are tested in lab experiments on thinking and reasoning. What North Americans might think of as sophisticated thinking—for example, sorting taxonomically (as in a robin being a kind of bird)—might be viewed as unsophisticated by the Kpelle, whose functional performance on sorting tasks corresponded to the demands of their everyday life (as in a robin flying). Here, Model I would fail to find an important difference in the Kpelle versus traditional Western and specifically European and North American ways of thinking. In a related fashion, Bruner, Olver, and Greenfield (1966) found that among members of the Wolof tribe of Senegal, increasingly greater Western-style schooling was associated with greater use of taxonomic classification.

Cole’s work built in turn upon earlier work, such as that of Luria (1931/1976), which showed that Asian peasants in the Soviet Union might not perform well on cognitive tasks because of their refusal to accept the tasks as they were presented. Models I and II would likely fail with such people, because people would be unwilling to accept the tests that are proposed to be universally applicable. Indeed, people in diverse cultures are presented with very diverse tasks in their lives. Gladwin (1970), studying the Puluwat who inhabit the Caroline Islands in the South Pacific, found that these individuals were able to master knowledge domains including wind and weather, ocean currents, and movements of the stars. They integrate this knowledge with mental maps of the islands to become highly respected navigators in their world.

In related work, Serpell (1979) designed a study to distinguish between a generalized perceptual deficit hypothesis and a more context-specific hypothesis for why children in certain cultures may show inferior perceptual abilities. He found that English children did better on a drawing task, but Zambian children did better on a wire-shaping task. Thus, children performed better on materials from their own environments that were more familiar to them.

Wagner (1978) had Moroccan and North American individuals remember patterns of Oriental rugs, and other individuals remembered pictures of everyday objects, such as a rooster and a fish. There was no evidence of a difference in memory structure, but evidence of a lack of difference depended precisely upon using tests that were appropriate to the cultural content of the individuals being studied. Moroccans, who have long experience in the rug trade, seemed to remember things in a different way than participants who did not have the Moroccans’ skill in remembering rug patterns. In a related study, Kearins (1981) found that when asked to remember visuospatial displays, Anglo Australians used verbal (school-appropriate) strategies, whereas Aboriginals used visual (desert nomad-appropriate) strategies.

Goodnow (1962) found that for tasks using combinations and permutations, Chinese children with English schooling performed as well as or better than European children; European children with Chinese schooling or those from very low-income families did somewhat worse than other children in their group. These re-

sults suggested that form of schooling primes children to excel in certain ways and not others (see also Goodnow, 1969).

Children from non-European or non-North American cultures do not always do worse on tests. Super (1976) found evidence that African infants sit and walk earlier than do their counterparts in the United States and Europe. But Super also found that mothers in the African cultures he studied made a self-conscious effort to teach their babies to sit and walk as early as possible. At more advanced levels of development, Stigler, Lee, Lucker, and Stevenson (1982; see also Stevenson & Stigler, 1994) found that Japanese and Chinese children had better developed mathematical skills than did North American children.

Carraher, Carraher, and Schliemann (1985) studied a group of children that is especially relevant for assessing intelligence as adaptation to the environment. This group of Brazilian street children is under great contextual pressure to form a successful street business. If they do not, they risk death at the hands of so-called “death squads,” which may murder children who, unable to earn money, resort to robbing stores (or are suspected of resorting to robbing stores). Hence, if they are not intelligent in the sense of adapting to their environment, they risk death. The investigators found that the same children who are able to do the mathematics needed to run their street businesses are often barely able or unable to do school mathematics. In fact, the more abstracted and removed from real-world contexts the presentation of problems, the worse the children typically do on them. For children in school, the street context would be more removed from their lives. These results suggest that differences in context can have a powerful effect on performance. (See also Ceci & Roazzi, 1994; Nuñez, 1994; Saxe, 1990, for related work.) In this work, Models I and II would fail to reveal that tests adequately measuring skills in the Brazilian street children are not the tests typically used to measure such skills in more developed countries.

Such differences are not limited to Brazilian street children. Lave (1988) showed that Berkeley housewives who successfully could do the mathematics needed for comparison shopping in the supermarket were unable to do the same mathematics when placed in a classroom and given isomorphic problems presented in an abstract form. In other words, their problem was

not at the level of mental processes but at the level of applying the processes in specific environmental contexts.

In summary, a variety of researchers have suggested that how one tests abilities, competences, and expertise can have a major effect on how “intelligent” students appear to be. Street children in Brazil, for example, need the same mathematical skills to solve problems involving discounts as do children in the United States about to take a high-stakes paper-and-pencil test of mathematical achievement. But the contexts in which they express these skills—hence, the contexts in which they can best display their knowledge on tests—are different (as in Model III described earlier). My colleagues and I have also done research suggesting that cultural context needs to be taken into account in testing for intelligence and its outcomes.

The measurement of intelligence may be viewed as occurring on a continuum from abilities to competencies to expertise (Sternberg, 1999a, 2003a, 2003b). All tests of intelligence, even the ones once believed to be culture-free, such as tests of abstract reasoning, measure skills that are at least in part acquired through the covariance and interaction of genes with environment. For example, a test of vocabulary found on intelligence tests is clearly a test of achievement. But so is a test of abstract reasoning, as shown by the Flynn effect, in which abstract reasoning skills showed substantial secular increases over the 20th century in diverse cultures around the world (Flynn, 1984, 1987). Hence, one can test knowledge as part of intelligence, but all tests of intelligence require knowledge, even if it is only knowing how to take the tests and to maximize one’s score on them.

Children May Develop Contextually Important Skills at the Expense of Academic Ones

Many times, investigations of intelligence conducted in settings outside the developed world can yield a picture of intelligence that is quite at variance with the picture one would obtain from studies conducted only in the developed world. In a study in Usenge, Kenya, near the town of Kisumu, investigators studied school-age children’s ability to adapt to their indigenous environment. They devised a test of practical intelligence for adaptation to the environment (see Sternberg & Grigorenko, 1997; Sternberg et al., 2001). The test of practical in-

telligence measured children's informal tacit knowledge for natural herbal medicines that the villagers believe can be used to fight various types of infections. Tacit knowledge is, roughly speaking, knowledge one needs to succeed in an environment, but it is usually not explicitly taught and often is not even verbalized (Sternberg et al., 2000). Children in the villages use their tacit knowledge of these medicines on average once a week in medicating themselves and others. More than 95% of the children suffer from parasitic illnesses. Thus, tests of how to use these medicines constitute effective measures of one aspect of practical intelligence as defined by the villagers, as well as their life circumstances in their environmental contexts. Note that the processes of intelligence are not different in Kenya. Children must still recognize the existence of an illness, define what it is, devise a strategy to combat it, and so forth. But the content to which the processes are applied—hence, the appropriate ways of testing these processes—may be quite different (as per Model III, described earlier).

Middle-class Westerners might find it quite a challenge to thrive or even survive in these contexts, or for that matter in the contexts of urban ghettos often not distant from their comfortable homes. For example, they would know how to use none of the natural herbal medicines to combat the diverse and abundant parasitic illnesses they might acquire in rural Kenya.

The investigators measured the Kenyan children's ability to identify the medicines, where they come from, what they are used for, and how they are dosed. They also administered to the children of the study the Raven Coloured Progressive Matrices Test (Raven, Court, & Raven, 1992), which is a measure of fluid or abstract reasoning-based abilities, as well as the Mill Hill Vocabulary Scale (Raven et al., 1992), which is a measure of crystallized or formal knowledge-based abilities. In addition, they gave the children a comparable test of vocabulary in their own Dholuo language. The children speak Dholuo in the home, English in the schools.

All correlations between the test of indigenous tacit knowledge and scores on fluid ability and crystallized ability tests were *negative*. The correlations with the tests of crystallized abilities were significantly so. In other words, the higher the children scored on the test of tacit knowledge, the lower they scored, on average, on the tests of crystallized abilities (vocabulary).

This surprising result can be interpreted various ways, but based on the ethnographic observations of the anthropologists on the team, Prince and Geissler (2001) concluded that a plausible scenario takes into account the expectations of families for their children. Many children drop out of school before graduation for financial or other reasons, and many families in the village do not particularly see the advantages of formal Western schooling. There is no reason they should, because the children in many families for the most part spend their lives farming or engaged in other occupations that make little or no use of Western schooling. These families emphasize teaching their children the indigenous informal knowledge that lead to successful adaptation in the environments in which they will really live. Children who spend their time learning the indigenous practical knowledge of the community may not always invest themselves heavily in doing well in school, whereas children who do well in school generally may invest themselves less heavily in learning the indigenous knowledge—hence, the negative correlations.

The Kenyan study suggests that the identification of a general factor of human intelligence may tell us more about how abilities interact with cultural patterns of schooling and society, and especially Western patterns of schooling and society, than about the structure of human abilities. In Western schooling, children typically study a variety of subject matter from an early age, thus developing skills in a variety of areas. This kind of schooling prepares the children to take a test of intelligence, which typically measures skills in a variety of areas. Often intelligence tests measure skills that children were expected to acquire a few years before taking the intelligence test. But as Rogoff (1990, 2003) and others have noted, this pattern of schooling is not universal and has not even been common for much of the history of humankind. Throughout history, and in many places still, schooling, especially for boys, takes the form of apprenticeships in which children learn a craft from an early age. They learn what they will need to know to succeed in a trade, but not a lot more. They are not simultaneously engaged in tasks that require the development of the particular blend of skills measured by conventional intelligence tests. Hence, it is less likely that one would observe a general factor in their scores, much as was discovered in Kenya.

What does a general factor mean anyway? Some years back, Vernon (1971) pointed out that the axes of a factor analysis do not necessarily reveal a latent structure of the mind, but rather represent a convenient way of characterizing the organization of mental abilities. Vernon believed that there was no single “right” orientation of axes; indeed, mathematically, an infinite number of orientations of axes can be fit to any solution in an exploratory factor analysis. Vernon’s point seems perhaps to have been forgotten, or at least ignored, by later theorists.

Just as I argue here that the so-called *g* factor may partly reflect human interactions with cultural patterns, so has Tomasello (2001) argued that so-called *modularity of mind* may in part reflect human interactions with cultural patterns. This is not to dismiss the importance of biology. Rather, it is to emphasize its importance as it interacts with culture, rather than simply to view it as some kind of immutable effect that operates independently and outside of a cultural context.

The partial context specificity of intellectual performance does not apply only to countries far removed from North America or Europe. One can find the same on these continents, as was done in the studies of Yup’ik Eskimo children in southwestern Alaska.

Children May Have Substantial Practical Skills That Go Unrecognized in Academic Tests

Related, although certainly not identical, results appear in a study done among Yup’ik Eskimo children in southwestern Alaska (Grigorenko et al., 2004). The investigators assessed the importance of academic and practical intelligence in rural and semiurban Alaskan communities. They measured academic intelligence with conventional measures of fluid (the Cattell Culture Fair Test of *g*; Cattell & Cattell, 1973) and crystallized intelligence (the Mill Hill Vocabulary Scale; Raven et al., 1992). (These tests, to some extent, reflect a Western bias in terms of what counts as “intelligence.”) They measured practical intelligence with a test of tacit knowledge of skills (hunting, fishing, dealing with weather conditions, picking and preserving plants, etc.) as acquired in rural Alaskan Yup’ik communities (the Yup’ik Scale of Practical Intelligence, YSPI). The semiurban children statistically significantly outperformed the rural children on the measure of crystal-

lized intelligence, but the rural children statistically significantly outperformed the semiurban children on the measure of the YSPI. The test of tacit knowledge skills was superior to the tests of academic intelligence in predicting practical skills as evaluated by adults and peers of the rural children (for whom the test was created), but not that of the semiurban children. This study, like the Kenya study, suggests the importance of practical intellectual skills for predicting adaptation to everyday environments. Can one find similar results in cultures that are urban and somewhat less remote from the kinds of cultures familiar to many readers?

Practical Intellectual Skills May Be Better Predictors of Health Than Academic Ones

In a study in Russia (Grigorenko & Sternberg, 2001), entirely distinct measures of analytical, creative, and practical intelligence (for details, see Grigorenko & Sternberg, 2001) were created, with at least two summative indicators for each construct. Principal components analysis, with both varimax and oblimin rotations, yielded clear-cut analytical, creative, and practical factors for the tests.

The main objective of this study was to predict, using the analytical, creative, and practical tests, mental and physical health among the Russian adults. Mental health was measured by widely used paper-and-pencil tests of depression and anxiety and physical health was measured by self-report. The best predictor of mental and physical health was the practical intelligence measure for mental and physical health, respectively. (Or, because the data are correlational, it may be that health predicts practical intelligence, although the connection here is less clear.) Analytical intelligence came second, and creative intelligence, third. All three contributed to prediction, however. Moreover, although the three abilities were the same (analytical, creative, practical); measuring them—especially the practical ones—required cultural adaptation that was appropriate for the Russian adults being tested (Model III).

The results in Russia emphasized the importance of studying health-related outcomes as one measure of successful adaptation to the environment. Health-related variables can affect people’s ability to achieve their goals in life, or even to perform well on tests, as was found in Jamaica.

Physical Health May Moderate Performance on Assessments

When interpreting results, whether from developed or developing cultures, it is always important to take into account the physical health of the participants one is testing. In a study in Jamaica (Sternberg, Powell, McGrane, & McGregor, 1997), the investigators found that Jamaican schoolchildren who suffered from parasitic illnesses (for the most part, whipworm or *Ascaris*) did more poorly on higher level cognitive tests (e.g., working memory and reasoning) than did children who did not have these illnesses, even after controlling for socioeconomic status. The children with parasitic illnesses did better on fine-motor tasks, for reasons unknown to us.

Thus, many children were poor achievers not because they innately lacked abilities, but because they lacked the good health necessary to develop and display such abilities. A person who is moderately to seriously ill probably finds it more difficult to concentrate on reading or listening than if he or she is well. Children in developing countries are ill much, and even most, of the time. They simply cannot devote the same attentional and learning resources to schoolwork that well children have to devote. Here, as in Kenya, their health knowledge would be crucial for their adaptation to the environment. Testing that does not take into account health status is likely to give false impressions.

Do conventional tests, such as tests of working memory or of reasoning, measure all the skills that children in developing countries can bring to the table? Work done in Tanzania suggests that they do not.

Dynamic Testing May Reveal Cognitive Skills Not Revealed by Static Testing

A study in Tanzania (see Sternberg & Grigorenko, 1997, 2002; Sternberg et al., 2002) points out the risks of giving tests, scoring them, and interpreting the results as measures of some latent intellectual ability or abilities. Schoolchildren between the ages of 11 and 13 years near Bagamoyo, Tanzania, received tests, including a form-board classification test (a sorting task), a linear syllogisms test, and a Twenty Questions Test ("Find a Figure"), which measure the kinds of skills required on conventional tests of intelligence. Of course,

the investigators obtained scores that they could analyze and evaluate, ranking the children in terms of their supposed general or other abilities. However, they administered the tests dynamically rather than statically (Brown & Ferrara, 1985; Feuerstein, 1979; Grigorenko & Sternberg, 1998; Guthke, 1993; Haywood & Tzuriel, 1992; Lidz, 1991; Sternberg & Grigorenko, 2002; Tzuriel, 1995; Vygotsky, 1978).

Dynamic testing is like conventional static testing in that individuals are tested and inferences about their abilities are made. But dynamic tests differ in that children are given some kind of feedback to help them improve their performance. Vygotsky (1978) suggested that the children's ability to profit from the guided instruction they received during the testing session could serve as a measure of their zone of proximal development (ZPD), or the difference between their developed abilities and their latent capacities. In other words, testing and instruction are treated as being of one piece rather than as distinct processes. This integration makes sense in terms of traditional definitions of intelligence as the ability to learn ("Intelligence and Its Measurement," 1921; Sternberg & Detterman, 1986). A dynamic test directly measures processes of learning in the context of testing rather than measuring these processes indirectly as the product of past learning. Such measurement is especially important when not all children have had equal opportunities to learn in the past.

In the assessments, children were first given the ability tests. Experimental group children were then given an intervention. Control group children were not. The intervention consisted of a brief period of instruction in which children were able to learn skills that would potentially enable them to improve their scores. For example, in the 20 questions tasks, children were taught how a single true-false question could cut the space of possible correct solutions by half. Then all children—experimental and control groups—were tested again. Because the total time for instruction was less than an hour, one would not expect dramatic gains. Yet on average the gains from pre- to posttest in the experimental group were statistically significant, and significantly greater than those in the control group.

In the control group, the correlations between pre- and posttest scores were generally high. One would expect a high correlation, be-

cause there was no intervention; hence, the re-testing was largely a measure of alternate forms reliability. More importantly, scores on the pretest in the experimental group showed only weak, although significant, correlations with scores on the posttest. These correlations, which were significantly and substantially less than those in the control group, suggested that when tests are administered statically to children in developing countries, they may be rather unstable and easily subject to influences of training. The reason may be that the children are not accustomed to taking Western-style tests, so they profit quickly even from small amounts of instruction as to what is expected from them.

Of course, the more important question is not whether the scores changed or even correlated with each other; rather, how did they correlate with other cognitive measures? In other words, which test was a better predictor of transfer to other cognitive performances on tests of working memory, the pretest score or the posttest score? The investigators found the posttest score to be the better predictor of working memory in the experimental group. Children in the dynamic testing group improved significantly more than those in the control group (who did not receive intervening dynamic instruction between pre- and posttests).

In the Jamaica study described earlier, the investigators had failed to find effects of an antiparasitic medication, albendazole, on cognitive functioning. Might this have been because the testing was static rather than dynamic? Static testing tends to emphasize skills developed in the past. Children who suffer from parasitic illnesses often do not have the same opportunities as well children to profit from instruction and acquire skills. Dynamic testing emphasizes skills developed at the time of test. Indeed, the skills or knowledge are specifically taught at the time of test. Would dynamic testing show effects of medication (in this case, albendazole for hookworm and praziquantel for schistosomiasis) not shown by static testing?

The answer was “yes.” Over time, treated children showed an advantage over children who did not receive treatment, and were closer after time had passed to the control (uninfected) group than were the untreated children. In other words, conventional static tests of intelligence may fail to reveal fully children’s intellectual potentials. Thus, when tests are mod-

ified in different environments, as per Model III, one may wish to modify not only their content but also the form in which they are administered, as was done in the dynamic testing.

CULTURE-FAIR AND CULTURE-RELEVANT TESTING

A culture-fair test is equally appropriate for members of all cultures and comprises items that are equally fair to everyone. Believers in culture-fair tests generally follow Model I, described earlier, for the relation between culture and intelligence. This approach is illustrated by Zeidner, Matthews, and Roberts (2004), who state:

As in other multicultural nations [besides Israel], research has been directed toward sociocultural differences in test scores. Because the tests are translated from English, any comparison of groups rests on the assumption that test adaptation is “culture-fair.” . . . The basic principal [*sic*] guiding the development of all major Hebrew standardized test versions was to stay as close to the English original as possible, unless items lacked compatibility with Israeli culture or the psychometric attributes of the items in the Israeli samples needed upgrading. (p. 220)

In this approach, minor adaptations are made. For example, Israel uses a different calendar (the Jewish one) than does the United States; hence, an adaptation was made for the proper year and time references. But these differences are quite minor.

Researchers compared the performance of Jewish examinees of Western and Eastern (Asian/African) backgrounds and found that on the Wechsler Preschool and Primary Scale of Intelligence and Wechsler Intelligence Scale for Children—Revised (WISC-R) the children of Western origins outperformed the children of Eastern origins. The difference tended to increase with age (Lieblich, 1983; Minkowitch, Davis, & Bashi, 1982; Zeidner, 1985). Ethnic group had a larger effect than socioeconomic group, although both mattered.

Comparisons of Israeli Jewish children with Israeli Arab children showed an advantage for the Jewish children of approximately one standard deviation (Kugelmass & Lieblich, 1975; Kugelmass, Lieblich, & Bossik, 1974; Lieblich, 1983; Lieblich & Kugelmass, 1981). Christian Arab children tend to outscore Muslim and Druze students on Raven’s Matrices (Bashi,

1976). Differences tend to be larger on nonverbal than on verbal tests.

Similar results have been found elsewhere. Savasir and Sahin (1995) found that Turkish children score about 12 points lower on the WISC-R than do American children. On the Gesell Developmental Schedules, Cantez and Girgin (1992) found that Turkish children generally lagged behind in the norms created for American children. In general, children from the educational systems in rural Turkey, which are less Westernized, have lower scores on translated Western intelligence and educational tests than those from educational systems in urbanized Turkey, which are more like Western systems (Kağıtçıbaşı, 1996; Kağıtçıbaşı, Sunar, & Bekman, 2001).

The etic approach is at least somewhat open to question. Because members of different cultures define intelligence differently, the very behaviors that may be considered intelligent in one culture may be viewed as unintelligent in another. Consider the concept of mental quickness. In mainstream U.S. culture, to say someone is "quick" is to say that the person is intelligent. Indeed, most group tests of intelligence are strictly timed. I found this out the hard way myself, when I failed to answer all or some of the items.

There can be no doubt that sometimes it is important to be fast. When you have not yet started writing a paper that is due the next day, it is definitely adaptive to be quick. An air traffic controller had better be fast if he or she values the lives of the passengers on the airplanes he or she is monitoring. In many cultures, however, quickness is not so valued. People elsewhere may believe that more intelligent people do not rush into things. In fact, early in the 20th century, a leading psychometric theoretician of intelligence, Louis Thurstone (1924), defined "intelligence" as the ability to withhold an instinctive response. In other words, the smart person does not rush into action but thinks first. Even in our own culture, no one is viewed as brilliant who decides on a marital partner, a job, or a place to live in the 20 to 30 seconds it might normally take to solve an intelligence test problem. So is it culturally fair to include a speed or timing component in an intelligence test?

Performance on tests that have been labeled "culture-fair" seems to be influenced by cultural factors. Examples are years of schooling and academic achievements (e.g., Ceci, 1996).

In summary, one must be careful when drawing conclusions about group differences in intelligence (Greenfield, 1997; Loehlin, 2000). The conclusions that appear to be justified on the surface may represent only a superficial analysis of group differences.

In the proposed model of culture and intelligence, Model III, tests are adapted in form and content to take into account the differences in adaptive tasks that individuals confront in diverse cultures, within and across countries. Individuals in other cultures often do not do well on our tests, nor would we do well on theirs. The processes of intelligence are universal, but their manifestations are not. Investigators who want best to understand, assess, and develop intelligence need to take into account the cultural contexts in which it operates. We cannot now create culture-free or culture-fair tests given our present state of knowledge. But we can create *culture-relevant tests*, and that should be our goal. Developing culture-fair tests based on each culture's own definition of intelligence may be an unrealistic goal. But it is possible to provide culture-relevant tests that require skills and knowledge that are relevant to the cultural experiences of the test takers. The content and procedures are appropriate to the cultural norms of the test takers. For example, 14-year-old boys performed poorly on a task when it was presented in terms of baking cupcakes. But they performed well when the task was framed in terms of charging batteries (Ceci & Bronfenbrenner, 1985). Brazilian maids had no difficulty with proportional reasoning when hypothetically purchasing food. But they had great difficulty with it when hypothetically purchasing medicinal herbs (Schliemann & Magalhães, 1990).

CONCLUSION

When cultural context is taken into account, (1) individuals are better recognized for and are better able to make use of their talents, (2) schools teach and assess children better, and (3) society utilizes rather than wastes the talents of its members. We can pretend to measure intelligence across cultures simply by translating Western tests and giving them to individuals in a variety of cultures. But such measurement is only pretense. We need to be careful even when we try to measure the intelligence of various cultural groups *within* a society.

CHAPTER 23

Perception and Cognition

ARA NORENZAYAN
INCHEOL CHOI
KAIPING PENG

For more than a century, most psychologists have based their discussions of human thinking on the cardinal assumption that basic cognitive processes are the same for all normal adult human beings, whether in the plains of Central Asia, the villages of East Africa, or the urban centers of Europe and North America. Cultural differences influence the content of minds, or the domains of thinking to which cognitive strategies are applied. For example, children in the Amazon might categorize snake varieties with the same interest that children in suburban America categorize video game varieties. Although *what* people think about varies considerably across cultures, the very *habits of thought*—the information processing strategies that people use recurrently to know the world around them—have been assumed to be the same everywhere.

Several historical developments in psychology have conspired to uphold cognitive universality as a foundational assumption in much of theorizing and research. First, the origins of psychology have been profoundly influenced by biology (Benjamin, 1988), leading to an assumption of universality in at least two respects: Much research on the biological basis of human psychology is conducted analogically in

other species. But if we begin with the view that humans in one culture share psychological mechanisms with other species, it follows that these same psychological mechanisms are assumed to be shared universally within humans themselves. Furthermore, to the extent psychology is grounded in biology, it inherits the theoretical foundation of evolutionary theory as well (Barkow, Cosmides, & Tooby, 1992; Pinker, 1997). Because evolutionary reasoning depends on the assumption of a shared, species-wide genome, this theoretical foundation encourages psychologists to accept psychic unity as a given rather than as a testable hypothesis. Learning theorists who influenced much of early experimental psychology in the mid-20th century also believed they were looking at mechanisms that applied not only to all humans but also to most other animals. The cognitive revolution, from its earliest development until nearly the end of the 20th century, rejected the learning theorists' behaviorism yet embraced the same universalistic position that was undoubtedly encouraged by the analogy between the human mind and the computer: Brain equaled hardware, cognitive procedures equaled operating principles and native software (Block, 1995). Because the "inputs"

could be radically different across cultures given variation in ecological and social conditions, “outputs” in the form of beliefs and behaviors would also be radically different, without affecting the underlying cognitive architecture of the mind.

As the anthropologist Richard Shweder has observed, the major theoretical stances in 20th-century psychology presumed a “central processing device. The processor, it is imagined, stands over and above, or transcends, all the stuff upon which it operates. It engages all the stuff of culture, context, task and stimulus materials as its content” (1991, p. 80). But the idea of an autonomous “central processing device” that transcends ecology and context did not always dominate the landscape of psychology. Three major theoretical positions with a long history in psychology and the social sciences proposed that human thinking is profoundly attuned to the sociocultural contexts in which it naturally occurs.

The first challenge originated in none other than Wilhelm Wundt (1916), regarded as the founder of experimental psychology, who held the view that higher cognitive functions were affected by cultural practices, and that when cultures and histories diverged, cognitive processes also diverged. Thus, he proposed a cultural psychology that he termed *völkerpsychologie* or “folk psychology” to complement experimental psychology:

[Folk psychology’s] . . . problem relates to those mental products which are created by a community of human life [e.g., language, religion] and are, therefore, inexplicable in terms merely of individual consciousness, since they presuppose the reciprocal actions of many. . . . Individual consciousness is wholly incapable of giving us a history of the development of human thought, for it is conditioned by an earlier history concerning which it cannot in itself give us any knowledge. (p. 3)

A second significant early idea that culture fundamentally shapes thought was that of the influential Russian School of Lev Vygotsky (1978) and Alexander Luria (1971), and their associates in the West, including especially Michael Cole and his colleagues (e.g., Cole, 1996; Cole & Scribner, 1974). The Russian School continues to influence a wide range of contemporary research on culture and cognition (Cole & Hatano, Chapter 5, this volume; Hutchins, 1995; Lave & Wenger, 1991; Resnick, 1994;

Rogoff, 1990). According to Vygotsky, human cognition develops in a cultural context, which is the accumulated pattern of symbolic and nonsymbolic tool use throughout the historical existence of a group. To the extent that societies diverge in their historical trajectories, different activities and tools that become available then give rise to different cognitive tendencies.

A third influential idea elaborating the notion that culture influences thought has captured far more sustained attention in psychology and the social sciences than those of Wundt and possibly Vygotsky. The linguistic relativity hypothesis (Whorf, 1956) contends that the particular language people speak affects their thought processes. Given that linguistic conventions vary greatly across cultures, cognitive processes would also vary as a result.

As Tomasello has argued (1999), the idea that human cognition is fundamentally cultural can be understood in the context of an apparent puzzle in human evolutionary history. Humans are genetically highly similar to their primate relatives and, not surprisingly, share with them most of their basic cognitive repertoire. But superimposed on these similarities, humans distinctively possess a vast network of complex cognitive skills involving symbolic communication and complex reasoning skills, as well as elaborate tool use technologies, that are unprecedented in higher primate cognition. The puzzle is that these distinctive features of cognition and behavior emerged very recently, possibly no earlier than about 250,000 years ago (Foley & Lahr, 1997). Simply put, it is unlikely that so many of these human-specific sets of cognitive abilities arose by the usual slow processes of genetic variation and natural selection in such a short timescale. Rather, such rapid changes in cognition could be explained by the emergence of the evolutionarily novel human ability for transmitted culture that operates much faster than genetic transmission (Richerson & Boyd, 2005; Sperber, 1996). Cultural transmission allows information to be passed on not only genetically but also socially, through social learning mechanisms such as mimicry, imitation, instruction (Tomasello, Kruger, & Ratner, 1993), as well as by-products of communicative processes, such as gossip, conversations, and storytelling (Schaller, 2001). Thus, unlike the case of other primates, human children make use of a richly structured cultural context as they develop; this context channels their innate cognitive capaci-

ties in new directions and subsequently alters their behavior and cognition in profound ways (Norenzayan, Schaller, & Heine, 2006).

Human cognition is therefore culturally dependent in ways that other primate cognition is not. This dependence gives rise to cultural variation in cognition for two reasons. Human groups occupy vastly different ecological niches (Edgerton, 1971) that may evoke different cognitive habits to solve the same problems of human existence, and as a result, their social and psychological practices also diverge in response to the local conditions (D. Cohen, 2001). Moreover, the cognitive capacities that enable cultural transmission, such as imitation, are biased toward ingroup members, also encouraging the emergence of stable cultural variation (Henrich & Boyd, 1998).

This chapter reviews evidence concerning the assumption of universality of cognitive and perceptual processes (see Choi, Choi, & Norenzayan, 2004, for a review of cultural variation in judgment and decision making, not discussed in this chapter). The cross-cultural evidence reveals marked cultural differences in the cognitive strategies, or habits of thought, recruited to solve a given cognitive problem. Although researchers are only beginning to understand the mediating processes by which cultural experiences shape thinking, these cultural differences are likely tied to different construals of the self, ecological differences in visual environments, assumptions about the nature of the world, beliefs about the origins of knowledge, linguistic conventions, expertise or familiarity with certain domains of life but not others, and social practices that promote some cognitive strategies at the expense of others.

We focus on cultural variation in domain-general reasoning and perceptual processes, such as visual perception, attention, rule-based reasoning, exemplar-based classification, numerical reasoning, spatial reasoning, and perceptions of change. We do not examine the growing literature on cross-cultural regularity and variation in domain-specific reasoning. There are substantial regularities in some of the ways that people organize their perceptual and conceptual worlds, and these characteristic patterns are often observable from a very early age. The most convincing evidence deals with infants' understanding of the physical world (Baillargeon, 1995; Spelke, 1990; Spelke, Phillips, & Woodward, 1995), reasoning about biological entities across cultures by adults and

children (Berlin, Breedlove, & Raven, 1973; Medin, Unsworth, & Hirschfield, Chapter 25, this volume; Medin & Atran, 2004), and children's understanding of mental life across cultures (Avis & Harris, 1991; Callaghan et al., 2005; but see Lillard, 1998). For discussions of the cross-cultural evidence for domain-specific reasoning, see Atran, 1998; Atran, Medin, and Ross, 2005; Callaghan et al., 2005; Medin et al., Chapter 25, this volume; Medin and Atran, 2004; Nisbett and Norenzayan, 2002; Wellman, Cross, and Watson, 2001.

THE LINGUISTIC RELATIVITY HYPOTHESIS

The notion that cultural experiences influence thought is famously illustrated in the linguistic relativity, or Whorfian, hypothesis (Whorf, 1956), or the idea that the particular language people speak affects thought. After a period of intellectual stagnation and inconsistent results, a recent surge of systematic and compelling studies have examined and found some degree of support for this hypothesis (e.g., Levinson, 1996; Roberson, Davies, & Davidoff, 2000), although the precise psychological implications of these studies continue to be debated in the literature (e.g., Boroditsky, 2003; Levinson, Kita, Haun, & Rasch, 2002; Li & Gleitman, 2002; Gelman & Gallistel, 2004).

In an early attempt, Berlin and Kay (1969) examined color classification across cultures. They found that color names are assigned in terms of an orderly hierarchy. In the few cultures where there are only two color names, these are black and white. If a third color is added, it is red. The next three color terms are likely to be yellow, blue, and green, and so forth. Berlin and Kay also concluded that though boundaries of color terms vary across cultures and languages, the focal point of each basic color (e.g., the most prototypical red in an array of reds) is essentially the same. The work of Berlin and Kay has been interpreted to indicate that there is a universal, physiological basis to color classification.

The pioneering work of Heider and Oliver (1972; and subsequently Rosch) supported Berlin and Kay's analysis. Working with Dani tribesmen in New Guinea, whose language has only two basic color terms, Heider and Olivier showed color chips to Dani and English speakers, and then tested for recognition of the chips a few seconds later. Using this procedure, mem-

ory for color was largely independent of color vocabulary and, consistent with the proposal of Berlin and Kay, focal colors resulted in better memory than nonfocal colors for both English speakers (Americans) and the Dani. This work generally has been taken as clear evidence against the linguistic relativity hypothesis. However, it has been criticized on methodological grounds for its narrow scope and for lack of subsequent studies confirming the findings of the original studies with other tasks or linguistic groups (Hunt & Agnoli, 1991; Lucy, 1997; Lucy & Shweder, 1979; Saunders & van Brakel, 1997).

More recently, new research has emerged that questions the findings of Heider and Olivier (1972), and offers new evidence for the influence of linguistic color terms on color perception and memory. Roberson et al. (2000) sought to replicate and extend the original studies of Heider and Olivier (1972) with the Berinmo of Papua New Guinea, a hunter-gatherer people whose language has only five color terms. In a series of experiments, they found convergent lines of evidence for linguistic relativity in color perception and memory. Berinmo patterns of naming and memory were statistically more similar to each other than Berinmo memory was to English memory patterns; the recognition advantage for focal colors relative to nonfocal ones disappeared for both English speakers and Berinmo speakers when response bias was controlled for; category learning for focal versus nonfocal colors did not differ. These findings indicate that the Berinmo do not have an underlying cognitive organization of color that favors the foci of the eight English basic chromatic color categories (with the possible exception of focal red). Furthermore, Berinmo speakers' performance in color categorization was considerably poorer than that of English speakers, replicating Heider and Olivier's finding with the Dani. This was despite the fact that Berinmo and English speakers did not differ in a similar visual-spatial memory task that did not involve the color domain. This suggests that the poorer memory performance of the Dani and the Berinmo could be explained by their poorer color vocabularies rather than unfamiliarity with a formal test situation or lack of formal education, as Heider and Olivier suggested.

A recent effort to examine the linguistic relativity hypothesis in number marking was carried out by Lucy and his colleagues (Lucy,

1997; Lucy & Gaskins, 1997). Following an early study by Carroll and Casagrande (1958), they examined the extent to which linguistic differences in number marking affect thought. Yucatec Maya and many other languages (e.g., Chinese, Japanese) differ from English in number-marking patterns. In English, discrete shape is implicitly emphasized in many nouns. Therefore, English numerals directly modify their associated noun without shape information. In Yucatec, however, substance is implicitly emphasized in nouns, and Yucatec numerals are always accompanied by a numeral classifier that describes essential shape information needed to count the object. Does this differential emphasis on shape versus substance lead to different patterns of categorizing objects? In nonverbal classification tasks, participants were presented with a triad of objects that differed on substance or on shape (e.g., plastic box, cardboard box, a piece of cardboard). Consistent with the lexical structures of these two languages, Yucatec speakers showed a preference for material-based classification (cardboard box, cardboard), whereas English speakers showed a preference for shape-based classification (plastic box, cardboard box).

The effects of mathematical symbols on numerical reasoning (Dehaene, 1997) have been examined by K. F. Miller, Smith, Zhu, and Zhang (1995; see also K. F. Miller & Stigler, 1987). An interesting difference between the Chinese and English languages is that for certain blocks of numbers (especially the 10–20 block), the base-10 structure is less obvious in English than it is in Chinese. Does this structural difference between the two languages affect the way children learn to count? The answer is yes. The authors examined the development of counting in 3- to 5-year-old Chinese and American children. Results revealed a complex pattern of similarities and differences in number acquisition that indeed reflected the structural differences of English and Chinese counting systems. No differences in learning to count were found from 1 to 10, for which both cultures rely on rote learning and not-base-10 principles. But a difference emerged, favoring Chinese children, for counting in the second decade (10–20), where base-10 principles are first learned, and where Chinese has simpler and more consistent names for 10–20 that are more consistent with base-10 principles. No cultural differences were found

for counting from 20 to 99, where both Chinese and English converge on a common structure of number names. Finally, no cultural differences were found in tasks consisting of object counting and simple mathematical problem solving. Thus, the cultural differences selectively emerged only when the structural differences in number naming were implicated in the number acquisition task.

Whether linguistic differences in counting systems affect numerical reasoning has been investigated in a more dramatic fashion among small-scale cultures that do not have an elaborate number marking system. In a recent study, Gordon (2004) examined reasoning among the Piraha, an Amazonian group that has a one-two-many counting system (see also Pica, Lerner, Izard, & Dehaene, 2004, for a similar study and similar results with the Mundurucu of the Amazon). Two main findings emerged. First, counting tasks with varying cognitive demands showed that performance with quantities greater than three were poor. For example, Piraha speakers were shown an array of familiar items (e.g., sticks), and asked to match these items with the equivalent number of other familiar items (e.g., nuts). Results showed that Piraha speakers had great difficulty matching an array of items if the array contained more than three items.

Second, despite their poor counting performance for numbers that are not available in the Piraha counting system, participants' estimation errors in assessing the quantity of objects reflected a constant coefficient of variation; that is, the amount of error increased as a function of the magnitude of the target size. The ratio of this average error to the target size is a constant, suggesting adequate estimation of quantity. Piraha speakers' coefficient of variation was identical to that of English speakers. This indicates that Piraha speakers were sensitive to quantity, were trying hard to get the answers correct, but were insensitive to exactitude of numbers larger than three.

There is growing consensus in the literature that numerical thinking relies on two independent cognitive strategies: One is a primitive "analog" number sense that is sensitive to quantity but is limited in accuracy. This cognitive ability is independent of counting practices, can be shown to operate in human infants, and is shared by other nonlinguistic higher primates (e.g., Dehaene, 1997). Second, human infants appear to have a cognitive abil-

ity that is sensitive to the exactitude of small numbers, possibly up to about three items. But it is only with the emergence of linguistically coded counting systems and cultural practices of counting that children in some cultures are able to count with exactitude numbers larger than three (for other interpretations, see Carey, 2004; Gelman & Gallistel, 2004).

Another line of research, by Levinson (1996) focuses on linguistic variation in the coding of spatial location. Speakers of English and other Indo-European languages favor the use of body coordinates to represent the location of objects in relative terms (e.g., "The man is on the right of the house"). In contrast, other languages such as Guugu Yiimithirr (an Australian language) and Tzeltal (a Mayan language) favor absolute reference in fixed cardinal direction terms ("The man is west of the house"). Is this difference in linguistic convention implicated in cognition? Levinson and colleagues have examined this question in their program of research. In one study, they created nonlinguistic tasks that measured performance in locating objects and manipulated the sensitivity of the two spatial referent systems to rotation. As expected, speakers of Guugu Yiimithirr were unaffected by the rotation manipulation in locating objects accurately. English speakers, in contrast, were thrown off by the same rotation manipulation, being less accurate in locating the objects. In another study, Dutch and Tzeltal speakers were seated at a table and shown an arrow pointing either to the right (north) or to the left (south). They were then rotated 180° to a second table where they saw two arrows: one pointing to the left (north) and the other one pointing to the right (south). Participants were asked which arrow on the second table was like the one they saw before. Consistent with the spatial marking system of their languages, Dutch speakers chose the relative solution, whereas the Tzeltal speakers chose the absolute solution. Subsequent research has shown that contextual manipulations can induce English speakers to reason according to absolute spatial reference (Li & Gleitman, 2002). However this is not surprising given that cardinal location terms, although not salient, do exist in the English language. What is important is that habitual ways of reasoning are systematically related to the dominant ways of talking about space in a given culture.

Linguistic differences may affect reasoning not only about space but also about time. In

English, for example, time is discussed in *horizontal* terms, for example, when one says, “We are behind schedule,” or “Let’s move the meeting forward.” In Mandarin, on the other hand, time is talked about in *vertical* terms: Earlier events are said to be *shàng* or “up,” and later events are said to be *xià* or “down.” In a series of experiments, Boroditsky (2001) investigated whether thinking about time is affected by this linguistic difference. In one study, English and Mandarin bilinguals were shown fish swimming either vertically or horizontally on a computer screen. Then participants were asked questions about time, such as “Does March come earlier or later than April?” Mandarin speakers were faster to confirm that March comes earlier than April after seeing the vertical movement of fish (which is consistent with the Mandarin linguistic coding of time), whereas English speakers showed the reverse pattern. Interestingly, another study showed that English speakers could be explicitly taught to think of time vertically, which then resulted in patterns of thinking characteristic of Mandarin speakers.

A well-known experimental attempt to test a linguistic relativity hypothesis is Alfred Bloom’s (1981) work on counterfactual or hypothetical reasoning. Bloom noticed that the English language has an explicit linguistic device to code counterfactuals (the subjunctive mode; e.g., “If I were rich, I would travel the world”). Not so in the Chinese language, which instead expresses counterfactual meaning by relying on context, combined with the use of *if . . . then* statements. In a series of studies, Bloom gave English and Chinese speakers, as well as Chinese–English bilinguals, controlled counterfactual stories, and found that Chinese speakers did more poorly than English speakers in counterfactual reasoning. However, Au (1983) and L. G. Liu (1985) have criticized Bloom’s work, raising questions about the accuracy of the Chinese translations of the stories. Furthermore, there is little doubt that Chinese are capable of counterfactual reasoning in everyday life. The question, then, is whether the presence or absence of a simple linguistic device to mark counterfactuals facilitates or discourages counterfactual reasoning (Hunt & Agnoli, 1991). As we see later, a case may be made that hypothetical reasoning is less prevalent in Chinese culture than among Westerners, though for reasons that may have more to do with fac-

tors other than differences in grammatical categories.

To summarize, after an initial period of mixed findings, growing evidence appears to favor the contention that linguistic differences affect thought. Although the strong version of the Whorfian hypothesis—that thinking is entirely determined by the particular language spoken in a community—has long been abandoned, less strong versions of the hypothesis have received empirical support in a variety of cognitive domains. Linguistic differences may result in habitually different ways of thinking, because different languages force their speakers to attend to strikingly different aspects of the world (Slobin, 1996). Although there are ongoing debates and controversies in this burgeoning new area of research (Hunt & Agnoli, 1991; Li & Gleitman, 2002; Gelman & Gallistel, 2004; Levinson et al., 2002), solid evidence has been found for the cognitive effect of linguistic differences in the coding of spatial location (Levinson, 1996), color categories (Roberson et al., 2000), and numerical reasoning (Gordon, 2004; K. F. Miller & Paredes, 1996; Pica et al., 2004). The work supporting linguistic relativity has profound implications for cognitive psychology and, more specifically, for the cultural mediation of thought. To the extent that societies have diverged in their linguistic conventions, so would cognitive processes, to some degree. Clearly, however, more research is needed to examine the pervasiveness of the influence of language on thought. Furthermore, the tools of experimental psychology can be profitably used to examine in more systematic detail the cognitive processes that mediate the linguistic shaping of thought. Finally, it is important to distinguish linguistic effects from other cultural effects on thought, for example, effects due to social practices, beliefs, or expertise in a domain. This is particularly challenging given that nonlinguistic cultural patterns and linguistic conventions tend to be confounded within the same populations.

DEDUCTIVE REASONING IN TRADITIONAL NONLITERATE SOCIETIES

According to the Vygotsky (1978), human cognition develops in a species-specific medium, that of culture, or the accumulated pattern of symbolic and nonsymbolic tool use of a social

group. The various social activities that a child engages in interact with primitive, biologically given cognitive structures. The child gradually internalizes these social activities and develops ever more complex cognitive structures. Cultural variation in cognition emerges to the extent that societies experience different historical developments, which then lead to different social activities and tools, which in turn afford different thought processes that are congruent with the particular historical trajectories of societies.

A pioneering attempt to study how cultural-historical factors transform thought processes was an expedition to Central Asia by Luria (1971) in the early 1930s. The purpose of this project was to examine the effects of massive social and economic reforms in remote regions of Central Asia on the logical reasoning of Uzbek peasants. Luria presented simple syllogisms in a quasi-experimental format to four groups of people at different degrees of modernization: nonliterate women in remote villages, who did not participate in formal economic practices; nonliterate men engaged in traditional farming; young activists involved in collective farming (some of whom were minimally literate); and women attending teacher training schools (Scribner, 1977). If logical reasoning is a universal property of the mind that is impervious to historical changes, then no differences in logical reasoning would be observed among these four groups. However, to the extent that cognitive structures are transformed by historical change in socioeconomic and educational conditions, greater exposure to modernization would lead to more reliance on formal logic.

Luria (1971) found marked variation in logical reasoning. The strongest results emerged for syllogisms with contents *unfamiliar* to the villagers. Villagers living traditional lives had the most difficulty with problems that did not conform to their everyday experience, suggesting that their responses were driven by a concrete, knowledge-based approach to reasoning. In some extreme cases, this pattern led to the refusal of some individuals to engage in the logical reasoning task at all, on the grounds that the contents of the problems were unfamiliar, making the problem in principle unanswerable. For example, to one of Luria's unfamiliar problems—"In the far north all bears are white. Novaya Zemlya is in the far north.

What colors are the bears there?"—one participant responded, "But I don't know what kind of bears are there. I have not been there and I don't know. Look, why don't you ask old man X, he was there and he knows, he will tell you." (p. 271). In contrast, the same unfamiliar problems posed no difficulty to those who had some exposure to schooling.

Several studies on logical reasoning in traditional versus industrialized societies followed the Central Asian investigation by Luria. Most notable are studies conducted with the Kpelle and Vai in West Africa (Cole, Gay, Glick, & Sharp, 1971; Scribner, 1975; Scribner, 1977), as well as with Maya- and Spanish-speaking villagers in Yucatán, Mexico (Sharp & Cole, 1975, cited in Scribner, 1977). Several interesting conclusions can be drawn from the findings of Luria and these more recent studies. First, logical reasoning seems to be facilitated by Western-style schooling. Increases in performance are detected in people with 2–3 years of schooling. Second, when people are matched by age and schooling, there is little systematic cultural variation in performance among different nonliterate cultures. However, performance in such cultures is somewhat lower than that in comparable industrialized populations, such as the United States. Finally, the most important generalization is that the characteristic reasoning pattern in traditional societies is a preference for concrete thinking based on direct personal knowledge. Experimental evidence, as well as ethnographic accounts of everyday life, show that the low solution rates do not betray an absence of logical reasoning ability. Rather they indicate an unwillingness to *play the game of logic with the experimenter*, which dictates a hypothetical stance that is often inconsistent with personal knowledge. This fact is evident when the villagers are asked to justify their responses. Justifications overwhelmingly appeal to direct personal knowledge external to the logical problem itself. In the rare cases when people do mention the structure of the argument in their justifications, performance is high. This is true across individuals, as well as for each individual. Thus, whenever an individual agrees to play by the rules of logic, the capacity for logical reasoning with simple syllogisms is impeccable (Scribner, 1977).

However, as will become clear later in this chapter, this preference for concrete reasoning

is not limited to nonliterate societies. Highly educated, industrialized East Asian samples in China and Korea also are more likely than comparable Western samples to favor concrete, intuitive, knowledge-based reasoning. Thus, the preference for formal logical reasoning prevalent in Western cultures may be only partly the result of the introduction of modern institutions such as industrialization. Other cultural factors that historically have been tied to the Western intellectual tradition, such as adversarial debate, contractual relationships, theoretical science, and formalization of knowledge, may account for the development of formal logical reasoning as a rhetorical system central to these activities (Becker, 1986; Lloyd, 1990; Nisbett, Peng, Choi, & Norenzayan, 2001).

CULTURAL DIFFERENCES IN PERCEPTION

Whereas Vygotsky and Luria examined higher level reasoning processes, other cross-cultural researchers have looked at whether the cultural environment affects perceptual processes. Segall, Campbell, and Herskovits (1966) investigated cultural differences in visual perception, particularly visual illusions. Here we focus on their findings regarding the famous Müller-Lyer illusion. Visual perception is a richly structured cognitive capacity with which every normal-sighted human being is biologically endowed. However, these biologically given visual processes may interact with the ecological properties of the external world, and learned habits of visual inference may be formed as a result of such dependence on ecological regularities. But to the extent that the ecological conditions in which people live diverge, culturally different habits of inference may emerge, even if the biological potential for vision is the same everywhere. Because people in the same cultural group share more or less the same ecological milieu, this question can best be answered by examining natural variation in ecological conditions across human cultures.

Segall et al. (1966) investigated this question, focusing on one ecological variable—the degree to which the visual environment is carpentered. They proposed the “carpentered world hypothesis.” According to this idea, in industrialized cultures with a pervasive carpentered environment where right angles abound, people internalize several related

perceptual tendencies: to interpret nonrectangular figures as rectangular, to perceive figures in perspective, and to interpret them as two-dimensional representations of three-dimensional objects. These tendencies should enhance the susceptibility to some visual illusions, including the Müller-Lyer illusion (see Figure 23.1). Segall et al. predicted that people in carpentered environments should be more susceptible to this illusion than people in noncarpentered environments. Over a 6-year period, psychologists and anthropologists administered visual tests that included European and North American samples, as well as samples in several African societies and the Philippines. The results supported the hypothesis: Although the susceptibility to the illusion was found across cultures, the average susceptibility to the Müller-Lyer illusion increased as a linear function of the degree to which the environment is carpentered. Subsequent research (Stewart van Leeuwen, 1973) showed that African school-age children in Zambia, who lived in an urban, carpentered environment, showed more susceptibility to the illusion than did children in a rural, uncarpentered region of Zambia.

Perceptual differences between urban industrialized groups and traditional populations have also been found by Witkin and Berry (1975). In this case, however, some traditional populations are more similar to industrialized groups than to other traditional populations. Witkin and his colleagues demonstrated that there are substantial individual differences in the extent to which people “differentiate” or decontextualize an object from the field in which it appears (Witkin, Dyk, Faterson, Goodenough, & Karp, 1974; Witkin et al., 1954). People who do this readily are “field independent” and people who do so with more

FIGURE 23.1. The Müller-Lyer illusion. Participants are asked to decide whether one of the two horizontal lines is longer than the other (in fact, they are exactly the same length). The angles-out version (top) is judged to be longer than the angles-in version (bottom).

difficulty are “field dependent.” They had a number of tests to examine field dependence including the embedded figures test, which shows people’s ability to separate a simple object from a more complex background, and the rod and frame test. In the latter test, participants look into a long box, at the end of which is a rod surrounded by a frame. The participant’s task is to indicate when the rod is vertical. The rod and the frame can be tilted independently of one another. Field dependence is indicated by the extent to which the position of the frame influences judgments about the position of the rod.

Whereas Segall et al. (1966) examined the role of the physical environment, Witkin and his colleagues proposed that field dependence is in part the result of a social orientation toward people. An outward orientation toward the social environment encourages an orientation toward the field in general. Witkin and Berry (1975) found substantial cross-cultural differences in field dependence. Farmers who live in societies where they must coordinate their actions with others were found to be more field dependent than were people who hunt and gather, or herd animals for a living. The latter sorts of livelihoods require less coordination with the actions of others, and social, political, and economic role relations tend to be relatively simple. Industrialized peoples have levels of field dependence comparable to those of mobile hunter-gatherers and herders. Like mobile peoples, industrialized peoples have more freedom in their lives and relative simplicity in role relations. There is also experimental evidence that these different orientations cause different perceptual tendencies. Kühnen, Hannover, and Schubert (2001) temporarily induced independent versus interdependent self-construals among German participants. In the independent priming condition, participants thought about how they were different from their family and friends. In the interdependent priming condition, participants thought about their similarities to family and friends. Subsequently participants were given the embedded figures test that assesses perceptual processing devoid of any obvious social elements. As expected, an independent self-construal led to a more context-free or field-independent perceptual processing, whereas interdependent self-construal led to more context-bound or field-dependent processing.

HOLISTIC AND ANALYTIC REASONING

Nisbett and his colleagues have pursued the proposal that marked cultural differences in modes of reasoning may exist between not only modern industrialized and traditional populations but also the two industrialized cultural areas: the West (North America, Western Europe) and East Asia (China, Japan, and Korea). This research has been summarized by Nisbett and his colleagues (Nisbett, 2003; Nisbett & Masuda, 2003; Nisbett & Norenzayan, 2002; Nisbett et al., 2001; Peng & Nisbett, 1999) as holistic versus analytic reasoning.

Holistic thought involves an orientation to the context or field as a whole, including attention to relationships between a focal object and the field, and a preference for explaining and predicting events on the basis of such relationships. Holistic approaches rely on experience-based knowledge rather than abstract logic and are *dialectical*, meaning that there is an emphasis on change, a recognition of contradiction and the need for multiple perspectives, and a search for the “middle way” between opposing propositions. Analytic thought involves detachment of the object from its context, a tendency to focus on attributes of the object to assign it to categories, and a preference for using rules about the categories to explain and predict the object’s behavior. Inferences rest in part on decontextualization of structure from content, use of formal logic, and avoidance of contradiction.

This distinction between habits of thought rests on a theoretical distinction made in psychology between two reasoning systems. One system is relatively associative, and its computations reflect similarity and contiguity (i.e., whether two stimuli share perceptual resemblance and co-occur in time); the other system relies on more abstract, symbolic representational systems, and its computations are a reflection of rule structure (e.g., Neisser, 1963; Sloman, 1996). The distinction that Witkin et al. (1975, 1974) made between “field dependence” and “field independence” in the perceptual realm, discussed earlier, resembles the cognitive distinction as well. The definition of Nisbett and his colleagues (2001) is meant to include both conceptual and perceptual aspects of the distinction, and also applies to the belief systems they regard as underlying those differences.

Although both systems of thought are in principle cognitively available to all normal

adult humans, cultural experiences may encourage reliance on one system at the expense of another, giving rise to systematic cultural differences. These differences in cognitive orientation are believed to be rooted in the different social worlds of East Asians and Westerners today. East Asians are more interdependent in their socialization practices, values, and social behavior than people of European culture, who are in turn more independent. In studies in which participants are asked spontaneously to describe themselves, East Asian students generate self-descriptions that are more likely to reflect their social identities (“I am a Keio student”) or refer to relationships (“I am a brother”). Americans more often generate self-descriptions that reflect abstract personality traits (“I am curious”) than do Japanese participants (Cousins, 1989). Markus, Mullaly, and Kitayama (1997) found in one study that 50% of Japanese self-descriptions included references to ingroup members, in contrast to only 24% for Americans (see also Rhee, Uleman, Lee, & Roman, 1996). Social harmony is valued over debate and frank discussion in the East, to a far greater extent than in the West (Becker, 1986). (For reviews of the literature on social-psychological differences between Eastern and Western cultural contexts, see Bond, 1996; Fiske, Kitayama, Markus, & Nisbett, 1998; Kitayama, Duffy, & Uchida, Chapter 6, this volume; Markus & Kitayama, 1991; Triandis, 1989, 1995.)

If so, we might expect to find cognitive differences among contemporary peoples participating in Western and North American cultural contexts. Nisbett and his colleagues conducted a series of studies that investigated this idea. Most (but not all) experiments were conducted with college students, but similar results were obtained with nonstudent samples. East Asian participants were Chinese, Korean or Japanese, and were tested sometimes in their own countries in their native languages and sometimes in the United States. The great majority of “Westerners” studied were Americans. The results support several expectations in line with this hypothesis. Below we highlight some cross-cultural findings from this research.

Attention to Object versus Field

If Americans attend more to the object and less to the relations between the object and the field, we would expect them to be less field de-

pendent than Asians. To test this possibility, Ji, Peng, and Nisbett (2000) gave the rod and frame test to Chinese and Americans matched for mathematical ability. Chinese were found to be more field dependent than Americans.

Masuda and Nisbett (2001) investigated attention to field versus focal object using a different paradigm. They showed underwater scenes to Japanese and American participants. Each scene consisted of rocks, plants, inert animals, small fish, and “focal” fish, which were larger, brighter, and faster moving than the others. Immediately after observing the scenes, participants were asked to describe what they had seen. Japanese typically began by referring to the context (“It looked like a river”), whereas Americans usually began by referring to the focal fish. Americans and Japanese made equal numbers of statements about the focal fish, but Japanese made about 70% more statements about the field and twice as many statements about relationships involving inert objects in the background. Participants were subsequently shown a number of objects, some of which had been in the original scenes and others which had not, and were asked to identify whether they had previously seen the object. Some of the objects were shown in their original environments, and others were shown in environments not seen before. This manipulation made no difference to the accuracy of Americans, but the performance of Japanese was less accurate when the background was different. Thus object and field appeared to have been bound for the Japanese (Chalfonte & Johnson, 1996; Hedden et al., 2000). When an object was removed from the context, their memory for the object was poorer.

In a related task, Masuda and Nisbett (2005) examined cultural differences in “change blindness,” or a systematic failure to recognize marked changes in surroundings (Simons, 2000; Rensink, O’Regan, & Clark, 1997). For example, when people are asked to watch a videotape and count the number of ball passes between players, they consistently fail to notice the insertion of an unusual character into the scene, such as a person carrying an umbrella or even a person wearing a gorilla costume (Simons & Chabris, 1999). Furthermore, “change blindness” is evident even when participants are explicitly asked to search for changes in the visual field. Although participants often take a long time to detect major changes in a given scene, they are likely to de-

tect changes in salient, focal objects faster than in objects of peripheral interest (Rensink et al., 1997). Masuda and Nisbett (2005) showed American and Japanese participants scenes in which changes occurred in focal object information (i.e., color and shape) and contextual information (i.e., background and objects' location), and participants were asked to identify changes in the scenes. Americans were more sensitive to focal object changes than to contextual changes, whereas East Asians were equally sensitive both to the focal object and to contextual information. This again reveals a greater tendency to attend to focal objects at the expense of the field among analytic thinkers.

More recently, Kitayama, Duffy, Kawamura, and Larsen (2003) developed a new paradigm to test cultural differences in perception. Participants were presented with a square frame, within which was shown a vertical line (see Figure 23.2). Participants were then shown another square frame of the same or different size and asked to draw a line identical to the first line in either absolute length (absolute task), or in proportion to the height of the surrounding frame (relative task). The absolute task is facilitated by the ability to decontextualize, whereas the relative task is facilitated by a contextualized mode of perceptual processing. The results indicated that Americans were more accurate in the absolute task, whereas Japanese

were more accurate in the relative task. In a subsequent study, Kitayama et al. showed that Japanese living in America and Americans living in Japan showed an intermediate pattern of accuracy, suggesting possible acculturation effects on perception (although other interpretations, such as self-selection, or different affordances of the perceptual environment are possible; see Kitayama et al., 2003).

Recently Chua, Boland, and Nisbett (2005) examined more precisely the mechanisms underlying cultural differences in attention. Chua et al. showed Chinese and American students (matched for age and field of study) photographs, each representing a focal object on a complex background (e.g., a tiger in a jungle), while students' eye movements were measured. The results showed that Americans fixated more on focal objects than did the Chinese, and looked at the focal objects more quickly. Furthermore, over time Chinese dispersed their attention to the background more than did the Americans. These findings support the idea that cultural experiences affect what people actually attend to in a scene.

Differing orientations of the self may explain the differential attentional and perceptual processing of East Asians and Westerners (Kühnen et al., 2001b). But could it also be that the perceptual environments of East Asia and the West contribute to these differences? If objects are more distinct from the field in the American

FIGURE 23.2. The framed-line test (Kitayama, Duffy, Kawamura, & Larsen, 2003).

perceptual environment, attention may be captured mainly by the object. On the other hand, if objects are embedded in the field and boundaries between objects are more ambiguous in the Japanese perceptual environment, attention may be dispersed to the whole field. Earlier we examined evidence for the notion that carpentered perceptual environments enhance vulnerability to certain kinds of visual illusions (Segall et al., 1966). Miyamoto, Nisbett, and Masuda (2006) similarly examined the perceptual environments of Japan and the United States. They took pictures of urban scenes in small, middle-size, and large cities in both countries, by randomly sampling places in each city. Using these pictures as stimuli, they analyzed the physical features of the scenes, and found that objects sampled in the United States stood out from the scenes, whereas objects sampled in Japan were embedded in the scenes.

Causal Explanation, Prediction, and Hindsight

Americans are more inclined to decontextualize the object from its context than are East Asians. We might therefore expect that Americans would be inclined to explain events by reference to properties of the object, and that East Asians would be inclined to explain the same events with reference to interactions between the object and the field. There is much evidence indicating that this is the case (for reviews see Choi, Nisbett, & Norenzayan, 1999; Norenzayan & Nisbett, 2000). J. G. Miller (1984) showed that Americans were likely to explain both events that “had a good outcome” and events that “had a bad outcome” by invoking presumed properties of the actor. Hindu Indians explained the same events by reference to situational and contextual factors. Similarly, Morris and Peng (1994) and Lee, Hallahan, and Herzog (1996) have shown that Americans explain murders and sports events by invoking presumed dispositions of the individual, whereas Chinese and Hong Kong citizens explain the same events with reference to contextual factors.

Norenzayan, Choi, and Nisbett (2002) found that Korean participants were equally willing to make disposition-based predictions in the absence of contextual cues; however, Koreans were more responsive to contextual factors when making predictions about how people in general would be expected to behave in a given situation and, much more than American

participants, made use of their beliefs about situational power when making predictions about the behavior of a particular individual. Importantly, Norenzayan et al. found that Koreans and Americans endorsed beliefs about the causes of behavior that accorded with their explanations and predictions. Koreans placed more credence in situational theories than did Americans. Choi and Nisbett (1998) found similar results when they examined circumstances in which both Americans and Koreans showed a correspondence bias; that is, they mistakenly attributed behavior to dispositions of a target actor who was operating under social constraints. However, Koreans were much more willing than Americans to revise their mistaken inferences about dispositions. Several other studies have replicated this pattern of results, indicating that although correspondence bias can be shown to exist in East Asian groups, it is much weaker among not only Koreans but also Japanese (Masuda & Kitayama, 2004; Miyamoto & Kitayama, 2002), and Chinese (Knowles, Morris, & Chiu, 2001; for an exception, see Krull et al., 1999). Furthermore, these studies have found that East Asian groups are generally much more willing than Americans to revise their dispositional attributions when social constraints on the actor are salient (e.g., Miyamoto & Kitayama, 2002; see Choi et al., 1999, for a discussion of these issues).

Explanation patterns are different even for nonsocial events. Morris and Peng (1994) and Hong, Chiu, and Kung (1997) showed participants cartoon displays of fish moving in relation to one another in various ways. Chinese participants were more likely than Americans to see the behavior of the individual fish as being produced by external factors, whereas American participants were more inclined to see the behavior as being produced by internal factors. Peng and Knowles (2003) also found that Chinese students with no formal physics education were more likely to perceive causality to originate externally to the target object (e.g., gravity, medium, friction, field), whereas a similar group of Americans referred to causes internal to the object (e.g., shape, weight, inertia).

Sensitivity to the role of contextual factors and attention to the field may have additional consequences. In a series of experiments, Choi and Nisbett (1998) found that Koreans were more susceptible to *hindsight bias*, that is, the tendency to believe that one could have pre-

dicted some outcome that in fact one could not have predicted. Choi and Nisbett argued that the East Asians' greater susceptibility to this bias might be due to the holistic tendency to attend to an ever-increasing number of contextual factors, and to a tendency to model events causally less explicitly. When a large number of possible factors are attended to, and when these factors are not explicitly represented, any given outcome can be readily explained by drawing on any number of interrelated factors, leaving little room for surprise or the experience of inconsistency, thus maximizing hindsight.

The cultural difference in causal explanation was found not only in the locus of attribution but also in the amount of causal information people consider to explain a certain event. East Asians have holistic assumptions about the universe, dictating that all elements in the universe are somehow interconnected; consequently, an event or object cannot be understood in isolation from the whole. In contrast, Westerners hold that the universe consists of separate objects that can be understood in isolation from one another. Therefore, East Asians are expected to consider a greater amount of information than Westerners to explain a certain event. Choi, Dalal, Kim-Prieto, and Park (2003) conducted a series of studies to test this prediction. They provided European American, Asian American, and Korean participants with a short scenario of a murder incident, along with a list of 97 items of information that might or might not be relevant to the explanation of the incident. Then participants were asked to eliminate the irrelevant information from the list. Choi et al. hypothesized that East Asians would find it more difficult than would Westerners to judge a given piece of information irrelevant and "not connected," and to eliminate it from further consideration. They found the expected pattern, such that Koreans were less likely than European and Asian Americans to discard a given piece of information.

Similarity and Relationships versus Categories and Rules

East Asians are more likely to group objects on the basis of similarities and relationships among the objects, whereas Americans are more likely to group objects on the basis of categories and rules. Ji, Nisbett, and Zhang

(2004) found that adults showed similar tendencies when asked about the association between words. Asked how strong the association was between words in a set, Chinese were more likely to find the association strong if there was a relationship between the words, either functional (e.g., pencil–notebook) or contextual (e.g., sky–sunshine), whereas Americans were more likely to find the association strong if the objects belonged to the same category (e.g., notebook–magazine).

Norenzayan, Smith, Kim, and Nisbett (2002) presented East Asians, Asian Americans, and European Americans with target objects and asked them to report whether the object was more similar to a group of objects to which it shared a strong family resemblance, or to a group of objects to which it could be assigned on the basis of an invariant unidimensional rule (see Figure 23.3). Thus, a schematic flower could be assigned to a group whose members it resembled most closely, or to a group whose members all shared a single feature that determined category membership (e.g., long stem). East Asians were more likely to regard the target as most similar to the group with which it shared a strong family resemblance, whereas Americans were more likely to regard the object as more similar to the group to which it could be assigned on the basis of the deterministic rule. Asian Americans' judgments were in between those of the other two groups.

Logical versus Dialectical and Intuitive Reasoning

East Asians are less likely than Westerners to decontextualize propositions and reason about them using formal rules. Furthermore, whereas Westerners reason about contradiction by applying a folk form of formal logic that aims to eliminate contradictions, East Asians reason about contradictions by emphasizing the "middle way" between contradictory propositions, or by tolerating opposites.

Experimental psychologists have found a "belief bias" in deductive reasoning: More plausible conclusions are judged as more logically valid than less plausible ones (Revlin, Leirer, Yop, & Yop, 1980). In one study, Norenzayan, Smith, et al. (2002) presented deductive arguments that were either valid or invalid, and had either plausible or nonplausible conclusions. They found that there was a difference in response bias, such that Americans

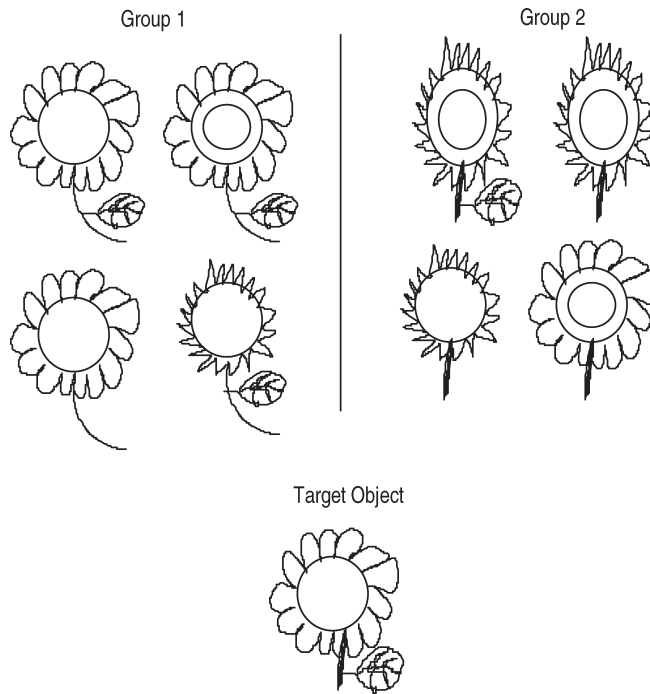

FIGURE 23.3. Example of the stimulus sets used in Norenzayan, Smith, et al. (2002, Study 2). Group 1 shares with the target object a strong family resemblance structure, but Group 2 shares with the target object a defining feature, in this case, the stem length (short or long).

overall showed a stronger tendency to judge arguments to be valid. However, regardless of this response bias, there was a culture \times conclusion plausibility interaction, such that the belief bias was greater for Koreans than for Americans, but for valid arguments only (see Unsworth & Medin, 2005, for a different interpretation). Importantly, this difference was not due to any difference in abstract logical reasoning ability between the Americans and the Koreans. Koreans' validity judgments were the same as Americans' when the propositions were formal and abstract. Thus, the difference between the two groups apparently resides in the willingness to decontextualize meaningful propositions sufficiently to be able to apply logical rules to their underlying structure.

An important aspect of the Western analytic stance is the belief that talking facilitates thinking. This is not surprising given that analytic thinking is intimately connected to linguistic representation of thoughts. This belief is so culturally ingrained that Western pedagogy takes it for granted that verbalization is a central part of learning. Talking is taken as a near-equivalent to, and direct evidence for, thinking,

as reflected in cultural practices such as debate and disputation in the Socratic method of teaching. In East Asian cultures, where an intuitive orientation is valued, however, talking is discouraged and silence is valued, as reflected in cultural practices such as silent meditation. Given the divergent cultural beliefs about talking, Kim (2002) examined whether the effect of verbalization on thinking is culturally specific. Asian Americans and European Americans thought aloud while solving reasoning problems such as Raven's Progressive Matrices. Talking impaired Asian Americans' performance but not that of European Americans. A follow-up study showed that talking impaired Asian Americans' cognitive performance, but articulatory suppression did not. Conversely, European Americans' cognitive performance was impaired by articulatory suppression but unaffected by talking. These results suggest that the underlying mechanism for the cultural difference is the differential use of internal speech in thinking. The exact relationship of these findings to the cultural differences in analytic versus holistic thinking remain to be examined. Talking recruits linguistic representa-

tion of the problem and as a result should facilitate analytic thinking but inhibit holistic thinking. An interesting open question, then, is whether the cultural differences regarding the effect of talking on thinking are generally the same for all modes of thinking, or whether they are especially pronounced for analytic tasks.

Many philosophers of science and ethnographers have pointed to a type of “dialectical” reasoning held to be characteristic of East Asians (S. H. Liu, 1974; Lloyd, 1990; Needham, 1962/1978; Peng & Nisbett, 1999; Spencer-Rodgers & Peng, 2003; Zhang & Chen, 1991). The orientation underlying this approach may be described (in a rather nondialectical fashion) as a set of three principles.

1. *The principle of change:* Reality is a process that is not static, but dynamic and changeable.
2. *The principle of contradiction:* Contradiction is a constant element of life.
3. *The principle of relationship or holism:* Nothing is isolated and independent; instead everything is related to everything else.

Taken together, these principles imply an attitude toward contradiction that is very different from that found in the West. Contradiction is to be expected and is not necessarily resolved. Propositions that appear contradictory on the surface may both contain some truth, and a constant goal is to search for the “middle way” between extremes.

Peng and Nisbett (1999) derived a number of predictions from the previous set of principles. Chinese collections of proverbs were found to have a larger proportion of “dialectical” proverbs containing contradictions (“Too humble is half proud”) than do English collections, and Chinese undergraduates were found to like dialectical proverbs more than did American undergraduates. Chinese were more likely than Americans to prefer arguments having a dialectical or holistic character rather than a logical structure. When asked to deal with inter- and intrapersonal conflicts, Chinese were more likely to say that both sides had some merit, whereas Americans were more likely to say that one side or the other was correct.

These different ways of reasoning also emerged in the way persuasive messages were

processed. When presented with a plausible proposition, both Chinese and Americans assented to it, but when participants were presented with both the plausible proposition and a less plausible proposition that appeared inconsistent with each other, Chinese and Americans responded in very different ways. Chinese became less confident about the plausible proposition, but Americans became even more convinced of the correctness of the plausible proposition! The Americans’ behavior is hard to justify on logical grounds, but it is understandable given Western insistence that a proposition must be true or false. Westerners’ arguments against the weaker proposition would serve to strengthen belief in the more plausible proposition. Chinese, in contrast, ended up believing that both propositions were about equally plausible, a tendency that is also hard to defend on logical grounds. This remarkable tendency can be understood as the result of Chinese desire to seek the “middle way” and to find the truth in apparently contradictory propositions.

These different modes of reasoning are also implicated in the ways that self-knowledge is organized. A series of studies revealed that among East Asian participants, self-knowledge is more contextual, flexible, holistic, and dialectical compared to that of European American participants (Spencer-Rodgers & Peng, 2004; Spencer-Rodgers, Peng, Wang, & Hou, 2004). In one study, when presented with either positive or negative feedback that was counter-schematic (i.e., inconsistent with prior self-concepts), Chinese were more likely than Americans subsequently to alter their self-beliefs, suggesting the Chinese had self-views that were more dialectical in nature.

The dialectical frame in East Asian cultures has important implications for reasoning about change in events. In a series of studies, Ji, Nisbett, and Su (2001) described various current states and asked whether participants thought the state would continue or change. For example, participants who were told about a man who grew up in a poor family were asked to predict whether he would remain poor in adulthood or grow rich one day. For each of four events, Chinese were more likely than Americans to think that the future would be different from the past. Ji et al. also presented to participants alleged, recent trends in world events about which participants were unlikely to have direct knowledge; for example, participants were told that the world’s economy has

been growing in the last decade, and they were asked to predict whether this trend would go up, go down, or remain the same. Chinese participants were more likely to predict that the next step would halt or reverse the direction of change, whereas Americans were more likely to predict that the trend would continue in a linear fashion. In one study, Chinese participants were more likely to predict reversals of trends in all but one of 12 cases (Ji et al., 2001).

Recently, Choi, Koo, and Choi (2005) devised a multifaceted self-report tool, the Analysis–Holism Scale (AHS), to measure analytic–holistic thinking style (e.g., “Everything in the universe is somehow related to each other”; “It is more desirable to take the middle ground than to go to extremes”; “It is more important to pay attention to the whole than its parts”). They then demonstrated that it adequately differentiated between-culture groups (Americans vs. Koreans) and within-culture groups (Korean students in Oriental medicine vs. other majors) as expected. Furthermore, the scale predicted analytic versus holistic solutions in tasks that measured attention, categorization, causal reasoning, and perceptions of change. Those with high scores on the AHS paid attention more to the field than to the object, categorized objects more based on similarity than on rules, considered a greater amount of information in causal explanation, and possessed a cyclic view of change more strongly than did those with low scores in the AHS.

Normative Considerations Regarding Culture Differences in Reasoning

So far our discussions of cultural variation in cognition have been descriptive, without addressing the related, important normative issue of how to evaluate the accuracy and practical value of different modes of thought. This is a particular challenge for the universalist position that argues for the “psychic unity” of humankind. If all of humanity shares the same invariant mental processes, how then do we explain cultural differences that are observed? The strong universalist position can offer two possible answers to this challenge. The first universalist answer views cultural differences in terms of a deficit model. In this view, there is a true universal human mind (often implicitly assumed to approximate the Western ideal), and any observed deviation from this ideal

mind is evidence for cultural or individual deficit. In this view, cultures may be ordered in terms of having more or less of an inherently desirable thing (e.g., logical rules, the use of probabilistic principles). The second possible answer is that cultural differences are superficial appendages that mask underlying deep similarities.

We find both versions of this universalist position problematic. We disagree with the superficial culture interpretation, and we have presented in this chapter considerable evidence that cultural differences in cognition are real and central to cognitive functioning. Yet we also reject the deficit model of these cultural differences and consider them ethnocentric projections, unless it is established that the same processes are valued across cultures and to the same extent. Instead we favor evaluating modes of thought in terms of the task goals and the very cultural values and practices in which they are embedded.

Consistent with the view that normative judgments themselves vary across cultures, many East Asian scholars have noted that logic in East Asian cultures does not enjoy the normative status that it does in the West. In Japanese culture, for example, “to argue with logical consistency is thus discouraged, and if one does so continuously one may not only be resented but also be regarded as immature” (Nagashima, 1973, p. 96). These normative evaluations may even affect interpersonal judgments. Ji et al. (2001) found that people who see events as changing cyclically (a dialectical pattern of reasoning) are judged to be wise more so by Chinese participants than by Americans. Recently Buchtel and Norenzayan (2005) asked participants to rank the importance of acting in a logical or an intuitive manner in relatively impersonal and interpersonal contexts. Overall, Americans ranked logic higher than intuition, whereas Koreans ranked these two about equally. Moreover, Americans favored “being logical” more than Koreans did, whereas the opposite pattern was found for “being intuitive.” In a second study, American and Chinese participants read about a company manager who made a decision either consistent with a procedural rule or consistent with intuition, and were asked a variety of questions that assessed their impressions of the target. Of particular interest, Chinese judged the intuition-following actor to be wiser and more reasonable than the rule-following actor,

whereas Americans showed equal preference. These cultural differences were more pronounced in impersonal contexts and were attenuated or disappeared in interpersonal contexts, in which intuition was favored by all. Cultural differences in value judgments about reasoning in some contexts remind us that an important part of cross-cultural research is to remain watchful of inadvertently projecting one's own values and judgments about a cognitive tendency that is not valued as highly in one's own culture, but may be more highly valued in another cultural group (see Cole & Scribner, 1974).

The philosopher Stephen Stich (1990) has addressed the normative status of cultural differences in thinking by arguing that "there are no intrinsic epistemic virtues. . . . Cognitive mechanisms or processes are to be viewed as tools or policies and evaluated in much the same way that we evaluate other tools or policies" (p. 24). According to Stich (see also Resnick, 1994), if there are culturally diverse ways to conduct the business of everyday cognition, and if there are culturally diverse systems of justification that serve the needs of various cognitive communities, then the reasonable philosophical position would be to evaluate thinking in terms of the local standards of justification, as well as the specific task requirements and inferential goals that vary across contexts.

This is not to say that it is always unreasonable to criticize specific inferential practices, even by the standards of another culture, but that criticism must take into account task goals and cultural contexts. And if we decide to apply the normative criteria of formal logic and probability theory to these modes of thought, we find that the analytic and holistic modes of thought generate a medley of normative and non-normative outcomes. For example, in deductive reasoning, analytic thinkers tend to decontextualize more than do holistic thinkers, but in causal attribution, the former more readily commit the fundamental attribution error than the latter. Conversely, holistic thinkers are more accurate in covariation detection (Ji et al., 2000), yet they are more vulnerable to hindsight bias (Choi & Nisbett, 1998). Furthermore, in some of the research reported here, European Americans have been shown to make errors in their efforts to be logically consistent that actually result in *incoherent* judgments in the sense that one judgment actually

follows from the opposite of the other (Peng & Nisbett, 1999). These errors were avoided by East Asian participants, who, however, made logical errors of their own in their attempts to reconcile opposing views. Similarly, Masuda and Nisbett (2005) examined scene perception and found change-blindness in both American and Japanese samples; however, Americans showed more change-blindness for background objects, whereas Japanese showed more change-blindness for focal objects. Thus, neither the analytic nor the holistic mode guarantees accuracy in perception and reasoning as defined by probability theory and formal logical principles.

EXPLAINING CULTURAL DIFFERENCES IN ANALYTIC AND HOLISTIC THOUGHT

What are the origins of these cognitive differences? To answer this complex question it is important to distinguish between *distal* and *proximal* explanations. Distal explanations are historical analyses that involve social, economic, and even geographic factors (Norenzayan & Nisbett, 2000; Nisbett, 2003). Proximal explanations involve individual-level processes, including beliefs, knowledge, social experiences, and psychological orientations, that have been shaped by these historical developments, are identifiable at the individual level, and could be directly implicated in these cognitive differences. The attempt to answer the distal question must, of course, be speculative at this time, because it involves complex sociological and historical issues. Nisbett (2003; Nisbett et al., 2001) has noted considerable parallels between contemporary cognitive differences in holistic and analytic thought, and studies of ancient Chinese and Greek philosophy, mathematics, and science that have influenced modern East Asia and the West, respectively (Becker, 1986; Fung, 1983; S. H. Liu, 1974; Lloyd, 1990; Nakamura, 1964/1985; Needham, 1962/1978; Zhang, 1985). Although these two ancient cultures shared many similarities, their metaphysical belief systems were different. Early Greek and Chinese philosophy, science, and mathematics were quite different in their strengths and weaknesses. Many Greek philosophers looked for universal rules to explain events and were concerned with categorizing objects with precision, and with respect to their "essences." There was a marked

distrust of holistic approaches. Chinese philosophers, especially Taoists, were more pragmatic and intuitive, and were distrustful of formal logic and rational distinctions (Fung, 1983; S. H. Liu, 1974; Lloyd, 1990; Nakamura, 1964/1985; Needham, 1962/1978).

Following scholars in several fields (Becker, 1986; Nakamura, 1964/1985), Nisbett and his colleagues (2001) argued that the social and economic systems of the two countries encouraged their respective cognitive orientations. China was an agrarian society with strong obligations and clear role relations specifying how to deal with family, clan, and village, and with tight vertical control of social relations. Action was carried out in the context of many role relations. Harmony with one's fellows was believed to be a primary end of the society (Munro, 1969). In contrast, the economy of Greece owed more to herding, fishing, and trading than to cooperative agriculture.

A goal of harmony would tend to encourage attention to the field as a whole, whereas the individualistic stance might allow for the luxury of attending to the object alone. Attention to the field would encourage finding relationships between events in the field, whereas attention to the object might encourage attending to the attributes of the object to be able to categorize it and apply rules to it. The harmony goal would tend to discourage debate and encourage consensual heuristics, such as *dialecticism*, that seek the "middle way" and the resolution of opposing positions (Lloyd, 1990). The consequence of the practice of debate is an emphasis on logical consistency and the avoidance of contradiction. Not surprisingly, pedagogical practices also reflect these cultural goals: Critical analysis and argumentation is emphasized in Western classrooms, and experience-based learning is emphasized in Chinese classrooms (for a review, see Tweed & Lehman, 2002).

The cognitive differences in reasoning to some degree mirror differences in philosophical traditions. As provocative as this congruence may be, it is difficult to know at this time whether these traditions are directly implicated in such reasoning processes, or whether the influence of these traditions on thinking is mediated through proximal factors.

At this time, the most compelling proximal explanation for the cognitive differences is the differing social orientations of people in East

Asia and Western cultures. As discussed earlier, East Asian children are socialized into a tight social network of mutual obligation and role relations, and, as a result, they develop an interdependent orientation of the self. In contrast, Western children from a young age are socialized into a social network of loosely connected, autonomous individuals, and, as a result, develop an independent orientation. An interdependent self-orientation may translate into context-sensitive information processing, whereas an independent self-orientation may encourage an object-focused processing. The cross-cultural evidence is consistent with this hypothesis: An analytic mode of processing is more prevalent in Western cultures, where people are also more independent, whereas a holistic mode of processing is more prevalent in East Asian cultures, where people are also more interdependent. However, research on the direct influence of these orientations on thinking has been sparse. Nevertheless, there is growing experimental evidence that inducing independent versus interdependent self-orientations affects analytic and holistic processing in predictable ways (Kühnen, Hannover, & Schubert, 2001; see also Kühnen & Oyserman, 2002).

A particular way of thinking is also transmitted and fostered through formal education in a society. For example, Koo and Choi (2005) reasoned that Oriental medicine reflects many aspects of East Asian holistic thinking, and hypothesized that the exposure to Oriental medicine training would foster the holistic way of thinking. They tested this idea by comparing the students of Oriental medicine and those of non-Oriental medicine in Korea in some cognitive domains. They found that the students of Oriental medicine believed in a cyclic pattern of change more strongly than did their counterparts. If a certain event had been increasing or decreasing, the students of Oriental medicine expected that the trend would reverse its direction in the future. They also thought that an event was determined by numerous factors, and that a given factor could not be dismissed easily while explaining a certain event. Therefore, they considered a greater number of factors in causal attribution. Importantly, a chronological trend emerged, such that holistic causal beliefs became stronger the longer students were exposed to training in Oriental medicine, and this trend remained after Koo and Choi accounted for age differences.

CAVEATS AND FUTURE DIRECTIONS

The accumulated evidence for cultural variation in cognition and perception is robust and reliable: These differences emerge from a variety of unrelated paradigms and methodologies, with a variety of samples, and many artifactual explanations have been ruled out (see Nisbett et al., 2001; Nisbett & Masuda, 2003). A meta-analytic review of studies comparing East Asians (Chinese, Koreans, Japanese) and North Americans (excluding Asian North Americans) indicated that the effect size for cultural differences is as strong for attentional and perceptual tasks as it is for tasks that involve language-based conceptual processes (Miyamoto, Kitayama, & Talhelm, 2006). Not surprisingly, East Asians tested in East Asian countries diverged more strongly than East Asians tested in North America. Now that there is convincing evidence that cultural differences in basic cognitive processes exist, two major challenges lie ahead for cultural psychologists. First, relatively little research has been done about the underlying proximal social-psychological factors that explain cultural differences in cognition. Second, most of the research has focused narrowly on comparisons of Western and East Asian participants, with relatively little attention given to most of the rest of the world's cultures, including both indigenous and industrialized populations in Africa, Latin America, Eastern Europe, the Mediterranean area, and the Middle East.

What factors encourage a holistic mode of processing in East Asian contexts and an analytic mode of processing in Western contexts? This important question is particularly complex, because multiple processes are likely to converge to produce the cultural differences, and disentangling them in the laboratory is a challenge. The hypothesis that different orientations of the self in these two cultures are causally responsible, as discussed earlier, has already received experimental support (Kühnen, Hannover, & Schubert, 2001). Further research can investigate this hypothesis in greater detail and establish the extent to which the cultural differences originate in different conceptions of the self. Although the use of self-report measures of cultural value orientations or self-construal across cultures are vulnerable to serious methodological problems (see Oyserman, Kimmelmeier, & Coon, 2002; Heine, Lehman, Peng, & Greenholtz, 2002), convergent methods that include valid self-

report measures, experimental methods, as well as population-level measures can be used in future cross-cultural research for this purpose. Other factors are only beginning to receive attention: differences in language (Ji et al., 2004; Tardif, 1996); residential mobility (Oishi, 2004); voluntary settlement patterns (Kitayama, Ishii, Imada, Takemura, & Ramaswamy, 2006); the perceptual environment (Miyamoto et al., 2006); exposure to different kinds of formal education within a culture, such as Oriental medicine or Western-style schooling (Koo & Choi, 2005; Scribner, 1977); and within-culture religious beliefs and practices (A. Cohen & Rozin, 2001; Sanchez-Burks, 2002). Greater concerted attention to within-culture analyses of the relationship of social and ecological experiences to cognition will propel cultural psychology into a second stage of inquiry, in which cultural differences in psychology are not only discovered but also explained in terms of the critical variables that produce and sustain cultural variation (Heine & Norenzayan, 2005).

More systematic cross cultural research programs are also needed that examine cultures outside of East Asia and Europe and North America (for an example of a research program on cognition in native American groups in Central America and the United States, see Medin et al., Chapter 25, this volume). Broadening the range of cultures under investigation is important for at least two reasons. First, it facilitates understanding of certain patterns of thought that are highly elaborated in other cultures but not well-represented in the samples currently under investigation. For example, Norenzayan (2005a) recently began exploring fatalistic thinking, characterized by a tendency to see outcomes in life as inevitable and multidetermined, and to attribute these outcomes to powerful agentic external forces, such as fate, destiny, or God. Fatalistic thinking is widespread in some regions of the world, such as in the Mediterranean area, and in many religious traditions. Not surprisingly, little is known about the psychology of this pattern of belief and thought given that it is an uncommon form of reasoning in the highly secular Western and East Asian samples that are the object of investigation in most of current cultural psychology.

Second, inclusion of more of the world's cultures allows greater opportunities to test specific hypotheses regarding the transmission mechanisms underlying cultural variation in

thinking. For example, if the differences between East Asians and Westerners in analytic-holistic thinking are explainable in terms of degrees of independence-interdependence, then other cultures where independence versus interdependence are prevalent should encourage analytic versus holistic processing, respectively. Kühnen, Hannover, and Roeder (2001) tested this hypothesis with participants in two individualistic cultures, United States and Germany, and two collectivistic ones, Russia and Malaysia, and found results consistent with this hypothesis in the domain of perceptual processing. Zebian and Denny (2001) compared integrative thinking (similar to holistic thinking) in a group of European Canadians to that in an immigrant Middle Eastern group with varying degrees of Western education, and found that the Middle Eastern group was on average more integrative than the European Canadian group. Furthermore, the authors found that exposure to a Western-style university education resulted in less integrative thinking among the Middle Easterners. Recently, Norenzayan (2005b) tested Canadian, Chinese, and Arab individuals in perceptual processing and deductive reasoning. Although the Chinese, as expected, showed more holistic processing than Canadians, Arabs were even more holistic than the Chinese! Similarly, Henrich (2005) examined classification and perception among the Mapuche, an indigenous group of farmers in southern Chile. Although the Mapuche have had little exposure to the cultural traditions of East Asia, their processing patterns were overwhelmingly holistic. Is it possible that the most interesting cultural divide is not the one between West and East, but between the West versus the rest? Are the cultures of the non-Western world, regardless of their cultural exposure to East Asian traditions, predominantly holistic in their cognitive outlook? Results like these invite more systematic investigation of the specific social and ecological variables that can account for such cultural variation.

CONCLUSIONS: UNIVERSALS AND CULTURAL PARTICULARS IN COGNITION

This chapter has examined how cognitive processes are shaped by the cultural context in which they occur. This is not to deny that basic process primitives appear in the human child at

a very early age and may have innate components. People everywhere are likely to possess cognitive strategies implicated in domain-specific reasoning, such as theory of mind, as well as domain-general ones that realize exemplar-based categorization, depth perception, long-term memory, covariation detection, and so forth. In fact, cross-cultural research is one of the principal ways that such process primitives can be uncovered (Norenzayan & Heine, 2005; Norenzayan et al., 2006; see also Cohen, Chapter 8, and Medin et al., Chapter 25, this volume). However, these primitive cognitive structures do not preclude the cultural dependence of human cognition.

A fruitful analogy is to think of the mind as a *toolbox* (Cole, 1996; Resnick, 1994; Stich, 1990; Vygotsky, 1978). Cognitive structures can be thought of as tools for everyday problem solving. Just as the handyman's specialized toolbox is accessed to construct and repair, the mental toolbox is accessed to solve myriad problems of everyday life. But to the extent that the worlds people inhabit are different (or are believed to be so), there emerge different affordances that elicit the use of different tools. In a world joined together by nails, a hammer is a more useful tool than a wrench. In a world held together by nuts and bolts, a wrench is a more useful tool than a hammer.

Based on this reasoning, Norenzayan and Heine (2005) discussed three distinct levels of universals that also encompass three kinds of cultural variation in cognitive processes, giving rise to four types of hierarchically organized classes. From strongest to weakest claims for cross-cultural universality, a cognitive phenomenon can be (1) an *accessibility universal*, if it emerges across cultures and in the same magnitude; (2) a *functional universal*, if it emerges across cultures in the same context but differs in magnitude; (3) an *existential universal*, if it exists in principle in the psychological repertoire of various cultures but is elicited by different contingencies and in different magnitudes; and (4) a *nonuniversal*, if it is absent from the psychological repertoire of some cultures. Below we briefly illustrate these distinctions.

At the shallowest level, there may be cultural differences in the cognitive accessibility of thought processes. Societies differ in the cultural practices they promote, affording differential expertise in the use of a cognitive strategy, or differential knowledge about a domain. The result is that a given cognitive process may

be equally available in principle, but differentially accessible in different cultures. As a result, the same phenomenon may emerge across cultures, but with systematically different effect sizes. An example of this is cultural variation in the correspondence bias in the attitude attribution paradigm, which refers to the tendency to attribute behavior to an actor's attitude, even when the actor is operating under social constraints. In most contexts, this bias appears in East Asian samples, but in a much weaker form (Choi et al., 1999).

Differential cultural expertise with a given cognitive process, or differential familiarity with a given domain, may yield an even more dramatic class of cultural variation in reasoning: In principle, people may possess similar cognitive repertoires, yet habitually rely on qualitatively different cognitive strategies in that repertoire to solve the same problems of everyday life. Thus, even if all cultures possessed similar cognitive toolboxes (i.e., existential universals), the tools of choice for the same problem may be different. In many studies reviewed in this chapter, the same problem triggered qualitatively different cognitive responses in the two cultural groups (see Nisbett et al., 2001). For example, confronted with apparently contradictory propositions, East Asians responded by trying to find the middle way, whereas Americans responded by polarizing their judgments. Research on logical reasoning among traditional peoples also reflects this kind of cultural difference. Whereas Western participants approach many kinds of problems by decontextualizing them and applying logical rules, traditional nonliterate folk approach the same problems by reasoning from their knowledge of the argument contents (Cole et al., 1971; Luria, 1931). Different levels of expertise in a domain may also lead to the use of different cognitive strategies to solve the same problem (e.g., Medin & Atran, 2004; Medin et al., Chapter 25, this volume).

Finally, the actual existence of particular cognitive processes may differ across cultures, in that different cultures may construct complex reasoning strategies out of universal primitive ones in feats of cognitive engineering, as suggested by Dennett (1995). The invention of symbolic systems such as calendars, number-naming conventions, pictographic and alphabetic writing, and formal logic provide examples. Beginning in the West in the 17th century, statistical, methodological, and cost-benefit

rules having applicability to scientific reasoning, as well as to policy analysis and everyday judgment and decision-making, began to be developed (Hacking, 1975). There is great variation among members of Western society today in understanding and using these rules. Similarly, Chinese philosophy developed the ancient Taoist notions of *yin* and *yang* into sophisticated ways of reasoning about change, moderation, relativism, and the need for multiple viewpoints. A case can be made that complex numerical reasoning that goes beyond one-to-many is contingent on a culturally available counting system (Gordon, 2004; Pica et al., 2004), and in that sense it is a nonuniversal. Quantity estimation, in contrast, appears to be invariant across cultures in magnitude and likely to be an accessibility universal. This framework highlights the fact that universality and cultural variability are not mutually incompatible and, in fact, theories in psychology can gain precision and generality by explicitly articulating both the invariant and culturally variable aspects of cognitive processes.

Human thinking occurs in a cultural context. Yet for most of its history, psychology proceeded as if the study of thinking is unrelated to the cultural environment in which the mind develops and functions. This picture has been changing with the growth of cross-cultural research that investigates the ways cultural experiences are implicated in human thinking. Cross-cultural research is the principal way—perhaps the only way—that legitimate inferences can be made about human universals, as well as about culture-specific patterns in cognition. As a result, the psychology of cognition and perception promises to be on firmer scientific ground to the extent that it encompasses the world's cultural diversity.

ACKNOWLEDGMENTS

The writing of this chapter was supported by a University of British Columbia Hampton Fund Research Grant No. 12R41699 to Ara Norenzayan. We thank the editors, Dov Cohen and Shinobu Kitayama, for their thoughtful comments.

CHAPTER 24

Narrative Reverberations

How Participation in Narrative Practices Co-Creates Persons and Cultures

PEGGY J. MILLER
HEIDI FUNG
MICHELE KOVEN

In *The Girl with the Brown Crayon: How Children Use Stories to Shape Their Lives*, Vivian Gussin Paley (1997) tells the story of a small black girl's passion for the books of Leo Lionni, a passion that transforms the kindergarten class and Paley's final year of teaching. The student, Reeny, is hooked first by *Frederick*, the story of a brown mouse whom she recognizes to be a kindred spirit. The students read and reread each book until they have memorized it. They discuss, ponder, and dramatize the story, and create posters that depict characters and scenes. Surprising things happen: Characters from different books turn out to be friends, Frederick shows up in a classmate's closely guarded fantasy world, previously inhabited entirely by rabbits. The Leo Lionni stories call forth other stories: epics from India, stories from a one-room schoolhouse in Mississippi, Harriet Tubman's adventures freeing slaves, including Reeny's great-great-grandmother. Paley notes that stories "proceed as if nothing else is going on" (p. viii).

In the process, they bring disparate people, places, and times into their orbit. By the end of the school year Reeny, the natural-born leader, innovator, and practitioner of the introspective life, is ready for first grade. Her teacher, contemplating an uncertain identity outside the classroom, faces many questions and a new beginning, but one in which the story of Reeny and Leo Lionni's stories will play a part.

We begin with this example because it dramatizes especially well how narrative reverberates through the lives of individuals, connecting them to other people, other stories, and other activities, and teaching them who they are or might become. Our goal in this chapter is to explain how narrative practices, such as those in Paley's classroom, are implicated in the co-creation of persons and cultures across the lifespan and across a variety of cultural contexts. Although the co-creation of person and culture is widely recognized to be a fundamental problem in cultural psychology, the mechanisms of this process have remained mysteri-

ous. We argue that everyday narrative practices can be fruitfully examined as one key site for how and where the co-creation of persons and cultures is accomplished.

The chapter is organized in the following manner: We first define practice approaches to narrative and identify some of the intellectual currents that have contributed to this perspective. We then engage the problem of the co-creation of person and culture at two disparate moments in the life course: early childhood and late adulthood. Growing literature shows that very young children participate in oral narrative, and that these “primary” stories are culturally differentiated from the beginning. At this very early moment stories are already implicated in the socialization process, drawing children into local systems of meaning and launching them along pathways toward particular versions of personhood. Without claiming to be exhaustive, we review work in this area, underscore important insights, and point to promising questions for future work. We then turn our attention to the other end of the life course. This literature is much more sparse, raising a host of questions. We use two examples of ethnographic work—Basso’s (1996) study of Western Apache narrative practices and Fung’s (2003) study of a Taiwanese grandmother’s story of her two marriages—to illustrate the cumulative consequences of decades of participation in narrative practices. At both ends of the life course narrative serves as a medium of both socialization, reproducing meanings and anchoring identities, and innovation and transformation, enabling people to alter their experience and reenvision their lives.

PRACTICE APPROACHES TO NARRATIVE

If meaning making lies at the heart of cultural psychology and narrative is a universal tool of meaning making, then the study of narrative is critical to furthering the most basic aims of cultural psychology. The process of negotiating and renegotiating meanings via narrative has been called “one of the crowning achievements of human development” (Bruner, 1990, p. 67). But what types of “meaning” does the analyst investigate? Cultural psychologists and scholars from allied disciplines have argued that the power of narrative cannot be fully appreciated without recognizing that it is a social practice, not

just a form of representation. In other words, the role of stories can be most fruitfully studied not only by examining the content and structure of stories but also by seeing narratives as embedded activities (e.g., Bauman, 1986; Miller, 1994; Wortham, 2001).

So, following the Reeny example, we could examine the referential meaning of the Lionni books, their themes and plots, to discern how the characters and actions are represented. Such an analysis might help us to understand part of why Reeny found these books so appealing. But it would leave out a great deal. It would leave out how Reeny and her classmates *used* these stories to make sense of themselves, one another, and the world. It would leave out the intensity and the varied modes of their engagement: listening silently with the whole body, memorizing, questioning, rewriting, disagreeing, dramatizing, and painting. It would leave out how friendships grew, faltered, and revived through and around these stories, and how the whole class cohered around a common frame of reference and an evolving set of narrative practices. And it would leave out the temporal trajectory of these stories: the history of how these children and teachers immersed themselves day after day in the Lionni stories, decontextualizing and recontextualizing them again and again (Bauman & Briggs, 1990).

A practice or sociopragmatic approach to narrative also raises questions that reach beyond the classroom itself. What did the various participants contribute to this emerging narrative community from their own cultural experiences? Apparently, Reeny’s avid interest and confident engagement in stories predated her arrival at kindergarten. When her mother, father, and grandmother make successive guest appearances at school, we hear the oral stories that are Reeny’s birthright. No wonder Reeny recognizes Frederick: “That brown mouse seem to be just like me!” (Paley, 1997, p. 5). Similarly, the Lionni stories remind Paley’s coteacher, who grew up in India, of the stories of the monkey prince that her mother and grandmother told her at bedtime, prompting her to share these stories with the children. Although the Lionni stories are fresh, new, and mind-expanding, they carry the children and teachers back to other stories, forming a narrative circle between home and school. Paley’s description illustrates that narrative cannot be sealed off from the rest of social life, a basic premise of practice approaches to narrative.

Premises of Practice Approaches to Narrative

The turn toward a practice approach to narrative is part of a larger trend toward practice-centered conceptions of language in cultural psychology and allied disciplines (e.g., Bauman & Briggs, 1990; Duranti & Goodwin, 1992; Goodnow, Miller, & Kessel, 1995; Ochs & Schieffelin, 1984; Shweder et al., 2006). These conceptions rest on the premise that to speak is to act—to create, perform, and transform social realities. A number of intellectual currents have fed into such practice-centered views of language, including scholarship that addresses the pragmatic features of talk—what people “do” with words (Austin, 1975) and sociocultural theory, with its focus on semiotically mediated activity (Cole, 1996; Wertsch, 1991). These perspectives converge on a conception of language that privileges the analysis of speech events in context (Bauman & Briggs, 1990; Bauman & Sherzer, 1989; Duranti & Goodwin, 1992; Hanks, 1996; Hymes, 1974; Jakobson, 1960). Hanks (1996) describes speech as “a form of engagement in the world. . . . To speak is to occupy the world, not only to represent it, and this occupancy entails various modes of expression, of which propositional meaning is only one” (p. 236). Terms such as “talk,” “speaking praxis,” “language use,” and “communicative practices” are therefore used to signal a contrast with the narrowly referential conception of language that holds sway in most research on human development and cross-cultural psychology. Instead of reducing language to a representational system or repository of knowledge, this approach recognizes the functional inseparability of talk and nonverbal action, and attends to how speech forms implicitly index or point to dimensions of interactional and sociocultural context (Silverstein, 1976/1995).

This approach enriches cultural psychology by expanding the toolbox of analytic techniques that scholars can use to examine talk as a cultural phenomenon. It allows the analyst to look at what participants “do” with each other in interaction—how, through talk, they position themselves relative to each other, and to broader sociocultural values and types of people.

Furthermore, because a practice approach assumes that words cannot be sealed off from silence or from gaze, posture, gesture, and other practices of the body, it allows the analyst

to treat talk (including narrative) as multimodal, inviting questions about how silence is patterned, and how verbal and nonverbal systems are choreographed and integrated.

In addition, a practice approach recognizes that speaking is organized beyond the sentence level into dialogues and genres (including a multitude of narrative genres). These larger communicative events and stretches of discourse, while serving as units of analysis, are themselves multiply embedded in larger sociocultural contexts and networks of cultural practices. In contrast to approaches that take the disembodied word, sentence, or text as the unit of analysis, this approach permits a deeper cultural analysis, for it recognizes that cultural principles are expressed not only in the content of talk but also in the way that discourse is organized internally and in relation to larger events and sequences of talk.

Creating Persons through Repeated Participation in Narrative

We said earlier that sociocultural theory is one of the intellectual currents contributing to a practice approach to narrative. Scholars working out of this tradition emphasize the routine or recurring nature of cultural practices, including narrative practices, in everyday life (e.g., Miller & Goodnow, 1995; Scribner & Cole, 1981). From this perspective, one way that cultural principles are expressed is in terms of the types of narrative practiced routinely. Several scholars have applied ideas from Vygotskian theory in an effort to understand the role that narrative plays in childhood socialization (e.g., Fivush, 1993; Nelson, 1989, 1996; Sperry & Sperry, 2000). For example, following Vygotsky’s account of the acquisition of scientific concepts, Miller (1994) proposed a discourse model of socialization in which institutions are organized to bring novices and members together recurrently for particular activities mediated by particular forms of discourse that lead to particular social and psychological consequences for the participants. As applied to the family, the institution in which early socialization occurs, the model posits that young children are socialized into systems of meaning through recurring interactions with family members that are mediated by narrative and other discursive practices. This approach to socialization has specific implications for empirical work, requiring that re-

searchers identify the kinds of narrative practices that young children routinely encounter in their everyday lives and the kinds of participant roles that are available to them.

Establishing the recurrent nature of narrative practices is especially important from the standpoint of the co-creation of person and culture. The power that narrative has to create certain kinds of persons rests in part on the frequency with which children participate in narrative. In the next section of this chapter, "Narrative in Early Childhood," we return to this issue. For now, we underscore two points. First, most research on children's narratives relies on elicited narratives; thus it cannot address the question of which narratives occur routinely in the child's life. Although elicited narratives can inform us about many important questions, observational and ethnographic studies are needed to address this question. Second, an important trend in research on the consequences of children's participation in narrative (and other cultural practices) is toward an expanded view of those consequences. Scholars argue that children not only acquire cognitive skills, such as the ability to tell stories to themselves and to other people, but they also develop selves and identities, affective stances, forms of moral agency, and ways of being (e.g., Fung, Miller, & Lin, 2004; Goodnow et al., 1995; Lave & Wenger, 1990; Miller, Fung, & Mintz, 1996; Rogoff, 1990; Wenger, 1998).

Creating Persons by Representing and Enacting Selves in Narrative

In addition to sociocultural theory, a variety of other theoretical traditions have treated narrative as a particularly rich type of discursive practice. This work, some of it familiar to cultural psychologists, draws from research on discourse in sociolinguistics that examines narrative "evaluation" (Labov, 1972; Labov & Waletzky, 1967), linguistic anthropology that examines "voicing" or "footing" (Bakhtin, 1981; Bauman, 1986; Goffman, 1979; M. H. Goodwin, 1990; Hill, 1995; Koven, 2002; Ochs & Capps, 2001; Voloshinov, 1973; Wortham, 2001) and conversation analysis (M. H. Goodwin, 1990; Jefferson, 1978, 1984; Mandelbaum, 1987, 1989; Sacks, 1974) that addresses the participant frameworks out of which stories emerge and which they transform. (See Koven, 2002, for discussion of these

several approaches.) Across these traditions, scholars investigate the "meaning" of stories not for their themes or plots but for the social actions participants accomplish. In such work, with its focus on "meaning" as interactional accomplishment, scholars have sometimes resisted addressing the psychological import of stories, out of a reluctance to see meaning as situated in and produced by the individual. However, with the stance that psychological meaning is deeply intertwined with social activity, such sociocentric accounts are perfectly compatible with current visions of cultural psychology.

More specifically, scholars taking a sociopragmatic approach have investigated how participation in narrative practices can construct participants' selves or identities (e.g., Bruner, 1990; Hill, 1995; Holland, Lachicotte, Skinner, & Cain, 1998; Miller, 1994; Ochs & Capps, 1996; Schiffrin, 1996; Urban, 1989). According to Wortham (2001), for example, narratives construct participants' identities insofar as narratives allow people simultaneously to enact and represent themselves in particular ways. Wortham argues that most attempts to understand how autobiographical narrative constructs and transforms the self are inadequate, because they analyze narrative only at the representational or content level. In other words, autobiographical narratives function not only to represent the self-protagonist in past events but also to position the narrator in relation to his or her audience in the here-and-now event of storytelling. He analyzes one woman's telling of her life story, showing how her description of herself as a character was mirrored by the stance she took toward her interviewer. While describing herself in the story as repeatedly moving from a passive to an active self over the course of her life, she simultaneously alternated positioning herself first as passive and vulnerable and then as active and assertive vis-à-vis the interviewer over the course of the interview. Wortham argues that such parallels, or "doubling," across representational and interactional levels of analysis constitute especially potent moments of self-creation and re-creation. Attention to the content of stories alone would miss how participants' selves are constructed in and through the storytelling interaction itself.

In keeping with this perspective, in a later section of this chapter, "Narratives in Late

Adulthood,” we discuss a Taiwanese grandmother’s narrative of her two marriages, which she had never shared with anyone, including her grown children. These intimate and intensely emotional events were tellable only to the ethnographer, precisely because she was an outsider to the family. We argue that the meanings that Mrs. Lin constructed about herself can be most fully appreciated by taking into account not only her narrative representations of her marriages but also the social circumstances that disallowed the telling of these stories to anyone but herself in the course of her everyday life.

NARRATIVE IN EARLY CHILDHOOD

In the Beginning, Personal Storytelling Abounds

By the time she entered kindergarten, Reeny was a veteran of narrative, steeped in oral stories about herself and her family. Surrounded as she was by gifted storytellers, we can surmise that she was exposed to stories from birth. Indeed, it is now well established that children from many cultural backgrounds within and beyond the United States begin to tell stories of personal experience in conversation during the second or third year of life (e.g., see reviews by Miller, Cho, & Bracey, 2005; Ochs & Capps, 2001; Shweder et al., 2006). At this early age, children step into the narrative practices of family and community, thereby laying claim to a vitally important cultural resource (Bruner, 1990). Even linguistically isolated deaf children, whose parents choose not to expose them to a conventional sign system, are able to create gestured narratives (Van Deusen-Phillips, Goldin-Meadow, & Miller, 2001). These stories carry hints of culture-specific meaning, suggesting that conversational narrative is a remarkably robust medium of socialization.

Young children’s stories of personal experience tend to be simple, invoking small departures from the baseline of their ordinary, expectable experience: A child gets a shot; shares, unprompted, with a sibling; goes to a birthday party; helps to cook a meal; writes on the bedroom wall; defends herself against a cousin’s aggression. Small events such as these have emotional or moral significance to the child and her family and are thus “reportable.” Consider the following example, in which the child Amy fell down and hurt herself, an unex-

pected event with obvious emotional import. This story was initiated by Amy’s mother: “She pulled a little sneaky the other day, went out the back door and fell down the back steps and busted her back all up. . . . Didn’t you? Went out there and fell.” Amy nodded her head, then said, “Me big fall down,” lifting up her dress to show the damage. Her mother replied, “You fell down, yeah [smiles]. You hit your back.” Although Amy was only 19 months old, she was able to contribute to this story of her own mishap, echoing her mother’s account, and adding a nonverbal embellishment (Miller & Sperry, 1988). Another child, age 3 years, launched a story about a memorable encounter during a recent family visit to the zoo: “Remember the walrus? . . . This is what he said ‘[makes spitting noises].’ ” Her mother replied, “Yeah, at the zoo. You went to the zoo again.” The child then repeated the walrus’s noise and enacted his surprising antics (Burger & Miller, 1999).

These stories may seem unremarkable, so mundane as to be negligible. From the standpoint of socialization, however, they are anything but negligible. Their power lies partly in their sheer abundance. Ethnographic observations of young children in the contexts of everyday family life show that telling stories of personal experience is a *recurring practice* in a wide variety of communities. For example, stories involving 2½-year-olds occurred at average rates of three to four per hour in both middle-class Taiwanese families in Taipei and middle-class European American families in Chicago (Miller, Wiley, Fung, & Liang, 1997). In a follow-up study of the same children at 3, 3½, and 4 years of age, stories of personal experience continued at similar rates (Chen, Lin, Miller, & Fung, 2005). Narratives accounted for one-fourth of 2-year-olds’ naturally occurring talk in working-class African American families in the Black Belt of Alabama (Sperry & Sperry, 1995, 1996). In working-class European American families in Chicago, 3-year-olds participated in conversations at an average rate of six times per hour (Burger & Miller, 1999). These and other studies suggest that the early years of life are a period of intense initiation into narrative. In interaction after interaction, personal storytelling gets woven, densely but almost invisibly, into the fabric of young children’s social experience. Before long, telling and listening to stories become second nature to them.

Early Storytelling Is Culturally Differentiated

Regardless of where they occur, these small, mundane stories are saturated with value and replete with culturally patterned messages. Personal stories vary within and across cultures along a variety of parameters that encompass how the genre is defined and practiced (Miller et al., 2005; Miller & Moore, 1989; Ochs & Capps, 2001).

For example, in her classic ethnographic study of neighboring, working-class communities in the Piedmont Carolinas, Heath (1983) found that members of Roadville, a European American community, adhered to a criterion of literal truth when narrating their personal experiences, a pattern that also occurred in the working-class communities of South Baltimore and Daly Park (Miller, Hengst, Alexander, & Sperry, 2000). This contrasted with the African American community of Trackton, where a "story" was not a story if it lacked fictional embellishment. Roadville and Trackton also enacted opposing norms toward denigration versus aggrandizement in their portrayals of the self-protagonist. Roadville children's stories occurred in response to adult invitations and focused on each child's own weakness or foolishness. Trackton children created bold, self-expressive, and triumphant self-protagonists, and asserted their right to tell stories by adroitly working their way into multiparty talk, commanding the floor and receiving approbation for their verbal artistry.

In their study of an African American community in rural Alabama, Sperry and Sperry (1995, 1996, 2000) found that 2-year-olds produced more fantasy stories than factual stories of past experience. "Both caregivers and children enjoyed telling stories of escaping from 'Nicoudini,' the 'Boogabear,' 'Werewolf,' or the spectral deer who entered their home one misty evening. Families told such stories easily and frequently, and children gathered around to be thrilled by the imagined terror and to practice creating it themselves" (Sperry & Sperry, 1996, p. 462). Caregivers actively discouraged girls' fantasy stories but were more accepting of boys' fantasy stories, a finding that may help to explain how men in this community get to be so good at "tall-bragging." Hypothetical stories, that is, stories about what could happen, were a relatively late development.

Another dimension of cultural variability in early storytelling has to do with the didactic use of stories. Several studies show that Chinese parents treat personal storytelling as an explicitly didactic medium (e.g., Van Deusen-Phillips et al., 2001; Q. Wang, 2004; Q. Wang & Leichtman, 2000; Q. Wang, Leichtman, & Davies, 2000; X. Wang, Bernas, & Eberhard, 2005). For example, Miller, Fung, and their colleagues conducted a series of comparisons of middle-class Taiwanese families in Taipei and middle-class European American families in Chicago, and found that the Taiwanese families were much more likely to tell stories in which they cast the 2½-year-old child-protagonist as a transgressor (Miller et al., 1996, 1997). In keeping with local beliefs that parents should take every opportunity to correct young children through concrete exemplars (Fung, 1999), many of these stories occurred immediately after the child had committed a misdeed in the here and now. In conarrated stories, and in stories told about the child in the child's presence, families repeatedly invoked moral and social rules, structured their stories so as to establish the child's misdeed as the point of the story, and concluded their stories with didactic codas.

By contrast, the European American families rarely told stories about young children's past transgressions. Even in those rare instances when a European American child's transgression was narrated, a qualitatively different interpretation was constructed, one that downplayed the misdeed or framed it as humorous (Miller et al., 1996). Thus, whereas Taiwanese families were more likely to use personal storytelling as a didactic resource for correcting young children and conveying moral and social standards, European American families were more likely to use personal storytelling as a medium of entertainment and self-affirmation. This contrast was also evident in parents' beliefs about storytelling (Miller, Sandel, Liang, & Fung, 2001) and in pretend play (Haight, Wang, Fung, Williams, & Mintz, 1999).

Moreover, the contrasting versions of personal storytelling practiced by the European American and Taiwanese families reflect and reinforce larger systems of cultural meaning in each cultural case. The self-favorability bias enacted by the European American families has been linked to discourses that valorize self-esteem (Miller et al., 1997, 2001); the didactic

bias enacted by the Taiwanese families has been linked to Confucian discourses that valorize teaching, listening, and self-improvement, discourses that continue to circulate in the complex mix of local and global influences that are reshaping child rearing and education in contemporary Taiwan (Fung et al., 2004).

In summary, studies of children's early storytelling in families and communities demonstrate that this narrative genre is culturally differentiated from the beginning. Wherever personal storytelling is practiced with young children, it takes on local color, absorbing values, affective stances, and moral orientations. As they participate routinely in personal storytelling, children not only imbibe values and acquire narrative skills but also begin to carve out different versions of personal experience. Personal storytelling thus highlights—and is implicated in—an early developmental moment in the co-creation of person and culture. Particular frameworks of evaluation and interpretation, linked to larger currents of cultural meaning, operate again and again in oral stories as narrators and listeners create and respond to here-and-now social contingencies. Each story conarrated with the child, each story told to a family member in the child's presence, provides another opportunity for the child to hear which experiences are reportable and how these experiences should be assessed. In this way, interpretive frameworks are not only reproduced but also repeatedly instantiated in personally relevant terms.

To return to the comparisons between European Americans and Taiwanese, we catch a glimpse of how culturally distinct selves might originate. One of the most intriguing findings of cultural psychology is that adult selves are culturally variable. For example, comparative studies challenge the assumption that the need for positive self-regard is universal, demonstrating instead that it is specific to North American culture, with its distinctive ideologies and philosophical traditions (Heine & Lehman, 2003; Heine, Lehman, Markus, & Kitayama, 1999). By contrast, Japanese selves have a more critical focus (Heine & Lehman, 2003; Heine et al., 1999), and the Chinese concept of personhood is rooted in the Confucian emphasis on a lifetime commitment to the continuously broadening and deepening process of self-cultivation, self-perfection, and self-transformation (Li, 2004a, 2004b; Tu, 1985,

1994; Q. Wang & Li, 2003). These findings about adults raise a critical developmental question: How do such culturally diverse selves come about? We propose that a need for positive self-regard is rooted, in part, in storytelling that is systematically biased toward self-favorability, whereas an inclination to self-improvement is rooted, in part, in the narration of misdeeds and the explicit invocation of moral standards. In the next section, we take a closer look at the roots of self-improvement, focusing on one Taiwanese child.

Co-Creating Persons and Cultures through Personal Storytelling

In the studies conducted by Fung, Miller, and their colleagues, youngsters from Taipei were exposed to one transgression story per hour on average (Miller et al., 1997). In the following lengthy example, described more fully by Fung et al. (2004), Yoyo (2½ years old) and his grandmother, Mrs. Lin, conarrated an incident that occurred earlier in the day, in which Yoyo committed two interlinked misdeeds: He knocked down a screen that divided the living room from the dining area, then protested when his mother spanked him. His grandmother initiated this story by saying, "Oh, yes, this morning, when Mom was spanking you, what did you say?" as she pulled Yoyo close and held him in her arms. Yoyo replied quietly, "[I] won't push the screen down [again]," while his grandmother lowered her head and leaned toward him to listen. In the ensuing 12 turns, she continued to review the incident with him, focusing her didactic efforts on his incorrect response—he had said, "Don't hit me!"—when his mother spanked him for knocking down the screen. His grandmother patiently pointed out where he went wrong and rehearsed in a hypothetical scenario what Yoyo should have said. Eventually, apparently satisfied that Yoyo now understood how he should behave when his mother corrects him, his grandmother explained to him that in the future he would be able to choose how to act: "Next time when Mom is going to spank you, which sentence is better for you to say to her?" Yoyo replied, "Hmm. Hmm. Say, 'I won't, I won't push the screen down.'" His grandmother replied, "Oh, yes, now you have choices. You say, 'Mom, I won't push the screen down.'" In that way, Mom won't spank

you. So next time when Mom is spanking you, you shouldn't say, 'You don't hit me [raises her voice and stamps on the floor with her right foot in imitation of YoYo's incorrect behavior]. You don't hit me [raises her voice and stamps on the floor again].' You shouldn't talk that way. . . . Instead, [if] you say to Mom, 'I won't push the screen down,' what would Mom do to you?" Yoyo then replied, "[She will give me] a tender touch." His grandmother repeated, "A tender touch," laughed loudly, picked him up, and held him tightly.

This conarration involved true-false questions, either-or options, repeated rehearsals, and a lesson that moved rapidly from the past, to the hypothetical, to the future. Without ever explicitly directing Yoyo to listen, his grandmother seemed to assume that even though he was only 2½ years old, he could follow a complex line of moral reasoning and learn from his past mistakes. And she seemed to trust that having learned, he would exercise sounder moral judgment in the future.

For his part, Yoyo was highly attentive to his grandmother throughout this protracted lesson. Most of his responses were of two sorts: he repeated words, preselected for him by his grandmother, or he assented verbally or non-verbally to her guidance. This pattern of responding might suggest that he was merely parroting what his grandmother said. Toward the end of the episode, however, he came up with his own novel response, one that surprised and delighted his grandmother. When Yoyo forecast that his mother would give him "a tender touch," he conveyed his faith that next time he would make the right choice, and that the right choice would restore him to his mother's good graces. In other words, as his grandmother expected, Yoyo not only listened and comprehended but also joined her to reflect upon his own behavior and project a better self.

Another important feature of this example is that it is the last in a series of five thematically linked retellings of the "same" events. These retellings unfolded over the course of an hour and a half and, at times, included Yoyo's older brother as conarrator, along with Yoyo and his grandmother (see Fung et al., 2004).

Thus, when this conarration is examined in the context of ongoing narrative activity, it is striking how much time and energy this family spent reviewing Yoyo's misdeeds. Equally striking, Yoyo accepted these critiques with patient forbearance, even when his older brother

joined in. Yoyo listened attentively, admitted to his wrongdoing, rehearsed rules for appropriate conduct, and imagined doing better in the future. The retellings of these misdeeds varied in subtle ways, highlighting different facets of the past events, making links to other events, and developing slightly different moral implications. This is typical of the way that children's transgressions are narrated in the Taiwanese families, but there was nothing remotely like Yoyo's narratives in our corpus of narratives from the European American families in Longwood; instead young children's misdeeds were edited out of the narrative record entirely, downplayed, or laughed about (Miller et al., 1996, 1997).

The narrative practices in Taipei, which are part and parcel of the child's daily experience, bring together again and again the ingredients of self-improvement, thereby helping to explain how children like Yoyo come to be self-improving persons—keen listeners and morally discerning agents, with strong attachments to caregivers and high standards of self-evaluation. Yoyo's family not only repeatedly narrated his past transgressions, constantly updating the currently relevant misdeeds requiring his attention but also zeroed in on particular lapses, subjecting them to intense moral scrutiny. These practices continued when Yoyo was 3, 3½, and 4 years old (Chen et al., 2005).

In her influential account of Inuit socializing "dramas," J. Briggs (1998) characterized the provocative questions posed by family members as "magnets" that drew the child's attention to any events that might provide clues to their meaning. Similarly, we argue that Yoyo's own misdeeds became magnets for his attention and imagination. Within this set of recurring practices—practices that were simultaneously narrative, moral, social, affective, and self-relevant—Yoyo over time became a more active participant (Chen et al., 2005). At 3½ and 4 years of age, he not only continued to listen carefully to his caregivers but he also initiated stories about his own and others' misdeeds, disagreed with others' accounts of his behavior, and engaged in complex moral reasoning about his past and future actions. In short, our argument is that the narrative practices described here constitute an early route toward self-improvement. Yoyo's habitual participation in these practices from such a young age not only naturalizes the project of self-improvement but also provides a distinct developmental pathway.

The Dynamics of Narrative Practices

When narratives are treated as situated practices, rather than disembodied texts, it becomes apparent that storytelling is a dynamic process, emerging from particular circumstances, shaped by the interests of narrating participants, recurring in different combinations, and affording children a range of participant roles. Children participate repeatedly with family members in networks of narrative practices characterized by systematic variability and crosscutting redundancies. In story after story they reproduce cultural frameworks and instantiate them in personally relevant terms. However, narrative is also a medium of innovation, a means by which individuals transform their experiences and identities (Holland et al., 1998; Wortham, 2001).

The dynamic nature of narrative practices is most apparent when narrators tell the “same” story repeatedly, as happened with the story in which Yoyo knocked down the screen, then protested when punished. In that example, other family members took the lead in reinvoking this story for Yoyo’s edification, expanding with each retelling the set of relevant associations. In the example presented at the beginning of this chapter, 5-year-old Reeny developed a passionate and infectious attachment to a written story. Children as young as 2 years of age develop similar passions—prolonged and intense attachments to particular stories, which they revisit again and again for weeks, months, and even years (e.g., Alexander, Miller, & Hengst, 2001; Engel, 1995; Miller, Hoogstra, Mintz, Fung, & Williams, 1993; Nelson, 1989; Wolf & Heath, 1992). The middle-class European American children in these studies treated their special stories as resources for discussion and pretense, and used them to ponder problems and to manage emotions, activities that were tolerated and supported by parents. These studies suggest that from the time young children enter into narrative sense making, they have the capacity to respond differentially to the ordinary narrative flow, seizing certain stories for especially active and intense engagement.

Most germane to the current point, however, are findings about how children’s repeated engagements with their special stories change over time. Some children use their stories to manage emotions, seeking out their special stories at moments of distress or conquering fear

evoked by the story itself through incremental, child-controlled engagement with the scary parts (Alexander et al., 2001). In one example, a child was initially so frightened by several incidents in a videotaped story that she hid in the corner of the room; some days later, she no longer hid but covered her eyes; eventually she watched intently the formerly scary segments, commented on them, and enacted them with her sister.

Miller et al. (1993) described a child’s attachment to “The Tale of Peter Rabbit” by Beatrix Potter. During the period from 23 to 24 months of age, Kurt produced six spontaneous retellings of the Peter Rabbit story. These retellings were not “copies” of the original story; rather, he incorporated stories of his own experience into the retellings, creating in effect a hybrid genre. Micro-level analysis of the content and plot of the successive retellings were conducted and revealed dramatic changes over time: Kurt successively appropriated and resolved conflicts posed by the written story, conflicts that paralleled concurrent experiences in his life. While retaining many elements of the Peter Rabbit story, he systematically transformed its plot, restoring harmony among the characters and canonical order to *his* world. Like the child who subdued her fear of the scary videotaped story, this child used his special story, in conjunction with stories of personal experience, as a tool of emotion regulation.

In addition to showing that very young children can transform their own experience through narrative, these studies also draw attention to three other important points. First, very few studies trace the “natural history” of stories over time; especially rare are studies that examine how stories operate over the long term in children’s lives. A compelling exception with older children is Cindy Dell Clark’s (2003) study of 5- to 8-year-olds with diabetes or severe asthma. One way that these children coped with chronic illness and frightening medical procedures was by imagining that a superhero from a favorite TV show kept them company. The superhero used his powers to protect the child during recurring moments of vulnerability. Second, these studies remind us that personal storytelling is not the only narrative genre that young children encounter; many youngsters inhabit worlds that are densely populated by written stories, stories from television and videotapes, and/or other genres of oral

narrative. We still know very little about the narrative repertoires of young children (but see Hicks, 1991; Kamberelis, 1993; Preece, 1987; Sperry & Sperry, 1995).

Third, the practice perspective on narrative that we outlined earlier draws attention to the many ways stories are embedded in, blended with, or otherwise keep company with other stories, other genres, and other activities. This emphasis on pervasive intertextuality is usually associated with Mikhail Bakhtin (1981), the Russian literary scholar and philosopher of language. From a Bakhtinian perspective, stories of personal experience qualify as a “primary” genre, in that they are simple and combine readily to form “secondary” genres (Miller et al., 2000; Ochs & Capps, 2001). In other words, the stories of personal experience that we described earlier not only provide young children from diverse communities and cultures, with readily available and culturally hued resources for making sense of their own experience, but they also become a mediating tool by which children forge personal connections to other stories. The example of Kurt interweaving stories of personal experience with stories of Peter Rabbit illustrates this especially well: He inserted himself into Peter Rabbit’s world and brought Peter Rabbit into his. As researchers apply Bakhtinian constructs to the analysis of children’s discourse, it is becoming clear that narrative sense making involves juxtaposing and interweaving multiple narrative genres and multiple, even conflicting voices and ideological perspectives, and that every community affords such heterogeneity (e.g., Cazden, 1993; Dyson, 1993; Hicks, 1994; Kamberelis & Scott, 1992; Miller et al., 2000; Taylor, 1995; Tobin, 2000; Wertsch, 1991; Wortham, 2001).

NARRATIVE IN LATE ADULTHOOD

Cultural psychologists and scholars from related fields have paid less attention to narrative at the other end of the life course. Because we have less information about the kinds of narrative practices in which older adults routinely engage or how these practices are culturally differentiated, this section of the chapter is necessarily more speculative. It does appear, however, that there are some parallels with early childhood. For example, the “primary” genre of personal storytelling, which emerges so early

in many groups, continues to be practiced by older adults. Although none of the studies of early narrative cited previously focused on older adults, stories of personal experience told by grandparents and other older adults formed part of the narrative environment that these youngsters inhabited (e.g., Miller et al., 2005). Another practice that extends into older adulthood is the use of stories of personal experience to mediate or personalize other stories, such as religious texts, histories of the group, or stories of ancestors (e.g., Basso, 1996; Hudley, Haight, & Miller, 2003). And just as very young children may become “attached” to certain stories, revisiting, savoring, or revising them again and again, adults may be haunted, baffled, or sustained for decades by stories from their own or others’ lives (e.g., Bruner, 1990; Coles, 1989; Fung, 2003; Gone, 1999, 2005; Hudley et al., 2003; Logan, 1989; Steedman, 1986). As the person tells the story repeatedly to self and others, it accrues layer upon layer of meaning and may be used to reinforce favored interpretations, to make sense or fail to make sense of events, to rationalize actions, or to construct new interpretations and craft new identities. Repeated tellings and reinterpretations of personal experience are institutionalized in psychotherapy, in religious conversion, and in Alcoholics Anonymous meetings (Holland et al., 1998; Spence, 1984; Stromberg, 1993).

Against this backdrop of continuity, there are obviously many differences between these disparate periods of life. Some older adults become narrative virtuosos (e.g., Bauman, 1986; Hudley et al., 2003), and in some cultural groups, people weave their stories of personal experience into overarching life stories, that is, oral stories of their lives over the long term (e.g., Linde, 1993; Peacock & Holland, 1993). In a recent collection of studies about narrative across the lifespan, Pratt and Fiese (2004) concluded that older adults’ stories are often “epochal,” embodying an appreciation of the sweep of history and of their own place in a generational trajectory, and that they use stories to ponder the meaning of their lives for themselves and for their offspring.

Western Apache Narratives and the Attainment of Wisdom

Older adults may use stories to socialize the young, as Yoyo’s grandmother did via stories of personal experience, and as Reeny’s teacher did

via written stories. In such cases older adults use stories to introduce cultural novices to valued ways of being and acting. But stories matter to older adults not just for their generativity; older adults may use narratives as tools of lifelong meaning making, plumbing the subtle meanings of stories, anchoring and reorienting themselves and other adults in a moral universe, remaking themselves if necessary. This process is exemplified in Basso's (1996) classic account of Western Apache narrative practices. Basso discovered that the Western Apache exploited two symbolic resources—land and narrative—for maintaining the moral order. Stories about the early history of the group were known to have happened at particular locations in the natural landscape. As people went about their daily business, they moved through a landscape that was saturated with moral tales, tales that “make you live right,” as one informant put it (p. 38), and they developed enduring ties to the stories and to the places where the stories had occurred. As a consequence of these bonds, people who behaved improperly were moved to reflect on and correct their misconduct. At times a member of the community might find it necessary to “aim” a story at an offender. If taken to heart, the story and the place with which it was associated would “stalk” the offender and promote beneficial change.

According to Basso (1996), a profound understanding of narrative was essential to the attainment of wisdom, as understood by the Western Apache. Because the path to wisdom was long and arduous, only a few individuals were able to persist and become truly wise. Wise men and women were highly respected and often lived to be very old. Wise people committed to memory a whole repertory of cautionary tales and reflected upon them at deeper and deeper levels. When a crisis arose, the wise person consulted these stories, determined which story fit the current situation, and used that story as a guide. “This is accomplished by picturing in one’s mind the exact location where the narrated events unfolded and imagining oneself as actually taking part in them, always in the role of a story character who is known to be wise” (p. 140). If a strong sense of identification occurred, this confirmed that the narrative would be helpful in the current situation; if not, another story was selected. Wise men and women were able to consult dozens of cautionary stories very quickly.

Once the appropriate story was identified, the wise person was able to see in his or her mind what needed to be done to resolve the current situation, thereby mending a quarrel or averting a disaster. Sometimes survival itself depended on the narrative interventions of wise people.

Basso's (1996) compelling account of Western Apache practices harkens back to a point made earlier in this chapter, namely, that narrative derives its constitutive power in part from the routinization of narrative practices in everyday life. Because stories permeate the land itself, stories are inescapable to community members, and wise people accumulate many years of experience engaging with these practices at ever deeper levels. This account also underscores that narrative practices are simultaneously public and private, interpersonal and intrapersonal. Stories mediate social relations and infiltrate people's hearts and minds. The internal mental landscape of wise people becomes just as densely populated with stories as the natural world in which they dwell.

This account is thus strongly resonant with Vygotsky's understanding of language and other semiotic resources as tools that are both publicly shared and privately utilized (Berk, 2001; Vygotsky, 1978, 1934/1987; Wertsch, 1985). According to Vygotsky, these resources originate in relationships between people, but eventually children are able to use them to communicate with others and with themselves. In a similar vein, Nelson (1996) concluded that language is more than a vehicle of enculturation: To a large extent “language and the surrounding culture take over the human mind” (p. 325), profoundly changing the nature of cognition and communication. The Western Apache case illustrates that this process continues through adulthood and may not reach its apogee until late in the life course.

Yoyo's Grandmother's Secret Stories

The extraordinary narrative achievements of Western Apache wise people are manifest both interpersonally and intrapersonally. But what about “secret” stories, stories that can only be told to oneself, that is, intrapersonally? In this section, we present and analyze an elderly Taiwanese widow's stories of her two marriages, stories that she could not share with significant others in her life. From a Vygotskian perspective, such stories are no less social than stories

told to a relative or friend; both involve social interactions—one with an actual person, the other with an imagined other. Moreover, complex social judgments are involved in the narrator's assessment that certain stories dare not be shared with others.

Untellability: A Preface to Mrs. Lin's Stories

The issue of tellability—or rather *untellability*—has received relatively little attention in scholarship on narrative (see Ochs & Capps, 2001). An untellable story is one that cannot be told to others without the risk of censure. In this section we take up an example of a story that raises the issue of the moral constraints on the tellability of a story. Narrators strive not only to be seen as good storytellers (Labov & Waletzky, 1967) but also as good persons. When people have personally challenging experiences that are potentially socially problematic, they may be compelled to keep such narratable events to themselves. That these events cannot be readily shared does not make them any less important. Indeed, their nonsharability may motivate the individual to keep these events alive through various forms of “private” narration.

The secret stories that caught our attention are the result of ethnographic serendipity, involving the same Taiwanese grandmother we quoted in the earlier example of Yoyo's narrated misdeeds. These stories were clearly of great, long-standing personal salience to Mrs. Lin, but were shared for the first time with another when told to the ethnographer. In this case, we see how participants may make use of the ethnographic encounter to narrate and enact stories in ways that would be considered taboo or inappropriate in their everyday lives. This highlights the importance of the socially untellable and people's creative use of novel speech events.

In the ensuing analysis, an important methodological issue emerges, one that is closely related to the conceptual issue of tellability. Typically, scholars of discourse analyze narratives that are told aloud and can be recorded. How can analysts study untellable stories, stories that are ordinarily told only to oneself in private, internal conversation? In the example at hand, we draw upon several sources of evidence: Mrs. Lin's narration of these stories to the ethnographer, her explicit admission that she had never before shared these stories with

another person, general background information about Taiwanese women's lives in Mrs. Lin's generation, and specific information about Mrs. Lin and her family.

Mrs. Lin's Stories: Untellable Except to the Ethnographer

Heidi Fung had known Mrs. Lin for 2 years when she asked to interview her about her child-rearing beliefs and practices. *A-ma* (a Taiwanese term for addressing elderly women, especially grandmothers) was in mourning over the loss of her second husband. Her daughter, Yoyo's mother, suggested that Fung take her to a restaurant and interview her there as a way to cheer her up. The researcher, therefore, conducted the interview with Mrs. Lin outside her home and away from her family. During that lunch, instead of answering Fung's questions, Mrs. Lin steered the interview in her own direction and insisted on telling stories about her two marriages. Fung found these stories to be so fascinating—so riveting, intimate, and emotionally powerful—that she met with Mrs. Lin on three later occasions over the course of a decade to talk with her further about her marriages (see Fung, 2003, for a detailed account).

What stood out in *A-ma*'s stories was a series of dreams about her first husband, Mr. Lin, all of which occurred after his untimely death at the age of 29. She reported that this was the first time that she had ever told anyone else about these dreams. She related that during the 30 days immediately following his death, he appeared to her every night in a dream. Even more remarkably, in the succeeding decades, he continued to appear in her dreams at key moments in her life (described later), up to the time of Fung's final interview, which occurred 45 years after his death. Each time Fung visited, *A-ma* was ready to share the dreams with her. Not only were the same dreams repeatedly narrated within the same session and across sessions, but there were always new dreams to tell. While the telling and sharing of her stories emerged out of the mutual trust that Fung and *A-ma* had built over the years, their relationship was also fostered by Fung's sympathetic listening and keen interest in Mrs. Lin's stories. *A-ma* had not found such responses in other contexts in her life, giving Fung privileged access to these previously private experiences. *A-ma* positioned Fung not only as an ethnographer but also as a woman with sufficient matu-

rity and marital experience to appreciate her dilemma. Because Fung was divorced, *A-ma* may also have recognized Fung as someone who had made a difficult decision in *her* life as a woman.

A-ma was 19 when she married for the first time. She deeply loved and admired Mr. Lin, a talented man who grew up in the same village with her and became a primary school teacher. She had resisted her family's efforts to arrange a marriage for her and was proud that hers was a "love marriage." With three children arriving in quick succession, life was a mixture of sweetness and strain. After 6 years of marriage, Mr. Lin passed away. *A-ma* was 25 years old. At the funeral, she vowed to him in Japanese,¹ "All our children, count on me (*wo chengdan le*)." She said, "Although I had always been a frail woman (*ruoruo de nyuren*), at that very moment, I suddenly became a man, I become a full man (*wanwan quanquan de nanxing*)." For the sake of their children, she transformed herself into a strong person to undertake the roles and responsibilities of both father and mother.

At age 38, after 13 years of widowhood, *A-ma* faced the daunting financial challenge of paying for the higher education of her eldest daughter, with two younger sons following close behind. One of her first husband's former students noticed her adversity and introduced her to Mr. Wang, a retired KMT military officer. The prospect of remarrying posed a painful moral dilemma for Mrs. Lin: Declining to remarry would preserve her fidelity to her beloved husband but imperil their children's education; agreeing to remarry would betray her husband but honor her vow to raise and educate their children. A devout Christian, *A-ma* made a deal with God, "If my daughter is going to be admitted to the [subsidized] normal college, I won't even give a thought to this matter [of remarrying]. This is how a mark had been made [between God and me]." When her daughter was admitted to a private college, *A-ma* was deeply disappointed but followed God's will. She married Mr. Wang.

On their wedding night something unexpected happened: Her first husband appeared to her in a dream. Subsequently, whenever *A-ma* moved or traveled afar, on the first night in the new locale, Mr. Lin would reappear. In these dream visitations, Mr. Lin simply stood in front of her bed looking at her without saying a word, leaving her to sob her heart out. Mrs. Lin interpreted these experiences to mean

that Mr. Lin followed her wherever she went, making his presence known to her at important moments in her life. It was his way of showing his continuing love for her and of reassuring her that he did not blame her for remarrying.² Consequently, Mrs. Lin believed that she did not need to feel guilty or ashamed in relation to her first husband.

However, Mr. Lin's dream visitations had profound and lasting consequences for *A-ma*'s life with her second husband. Over the 24 years of her marriage to Mr. Wang, which ended with his death, *A-ma* tried hard to decline a sexual relationship with him, and the tension between them was not released until Mr. Wang gradually lost interest in sex in his later years. In her conversations with Fung, *A-ma* described her remarriage as "selling her soul" for the sake of her children. Indeed, although Mr. Wang loved her dearly and helped bring up and provide the best education for her children, and although she was deeply grateful to him, she could never give him the kind of affection that she had given to her first husband. In other words, although on the surface, *A-ma* betrayed her faithfulness to her first husband, in reality, she stood firm in remaining loyal to him—spiritually, mentally, and physically.

Why Mrs. Lin's Stories Were Untellable

The foregoing reprise is a severely truncated description of the narrated events (Mrs. Lin's two marriages) and of the events of narration (Mrs. Lin's tellings of these events to the researcher in the successive "interviews") that a practice approach would require to do justice to Mrs. Lin's remarkable narrative of her two marriages. One would have to examine the transcripts of *A-ma*'s meetings with Fung for more details of the developing relationship between Fung and *A-ma*, and of the complex relationship between *A-ma*'s narration and the events narrated. However, this example does offer an opportunity to illustrate how attention to both levels of analysis can help to penetrate the meanings of such a complex story.

Over the course of the four tellings, Mrs. Lin became more forthcoming in what she revealed to the ethnographer. Although her children knew that she sometimes dreamed about their father, she did not tell them or anyone else about Mr. Lin's dream visitations or other intimate details of her marriages. These profoundly meaningful and emotionally powerful

experiences—the intense mutual love between Mrs. Lin and her first husband, the dreams surrounding his early death, and his continuing felt presence in her life, enduring through and beyond her second marriage—were not narratable in the contexts that she ordinarily inhabited. Thus, a defining feature of Mrs. Lin's everyday narrative practice was that she could not, or would not, narrate these experiences to the significant others in her life.

Why was this the case? And why did she make an exception for the ethnographer? Mrs. Lin herself said explicitly that she could only share her story with an outsider (*wairen*), someone who was not a member of her family. Perhaps the story—particularly the sexual details, which only gradually emerged across the several tellings—was too intimate to be shared with her own children. In addition, although Mrs. Lin treasured her first husband's visitations, she regarded them as mysterious and noted that her sister-in-law, widowed after 50 years of marriage, did not have similar experiences. Perhaps she wondered whether her highly educated, "modern" children would regard the visitations as bizarre and unsettling. We believe, however, that the most important reason for her reluctance to share her stories with her children was her conviction that her children would not be able to comprehend her unconventional actions. How could she make them understand that she "betrayed" their father to better *their* lives, and that she remained loyal to him and received his full support on her decision to remarry?

Mrs. Lin had good reason to fear that her children would not accept her version of events. Her children, especially her eldest son, had complex feelings about their stepfather, Mr. Wang. The eldest son refused to invite him to his wedding, a very disrespectful act that broke Mr. Wang's heart. Apparently, he felt that Mr. Wang had no place at a formal occasion that honored and furthered the Lin family line. According to the younger son, his older brother felt guilty because he had been unable to care for his mother and siblings for the Lin family. If he had fulfilled his responsibilities as eldest son, his mother would not have had to remarry. This implies some disapproval of Mrs. Lin's decision to remarry on the grounds that she dishonored the Lin family, echoing the traditional Chinese precept that "good" widows, no matter how young, should not remarry (Holmgren, 1985; Mann, 1987; Sommer,

1996; Waltner, 1981). Political currents also may have colored the children's feelings toward Mr. Wang. Unlike Mr. Lin, who was born and grew up in the same fishing village as Mrs. Lin, Mr. Wang came from mainland China and spoke a different dialect of Chinese. Whereas Mr. Lin was a literati and schoolteacher, Mr. Wang had been a member of the KMT army that retreated to Taiwan with Chiang Kai-shek in the late 1940s. His very different background and perhaps different political inclination likely aggravated the children's complex feelings about their mother's remarriage. In summary, we surmise that *A-ma's* marital life was a touchy topic within the family, leading her to doubt that her children would welcome or appreciate her story about her two marriages.

The ethnographer, on other hand, was not a member of the family, and *A-ma* first related her story to Fung outside the family context. Furthermore, Fung did not have complex feelings about Mrs. Lin's decision to remarry. Indeed, she admired *A-ma* for having the courage to take an anomalous path, forging a life of emotional truth and integrity as a woman. To have someone from the younger generation take such a strong and sympathetic interest in her narrative must have been gratifying to *A-ma*, affording her a context that she creatively appropriated to narrate the previously unsharable. Here is an instance of the "doubling" across representational and interactional levels of analysis (Wortham, 2001) that we discussed earlier. In the ethnographic encounter, Mrs. Lin found a recipient for her story, that is, a context that transcended the normative constraints on tellability that governed her everyday life. The singularity of this context paralleled the singularity of her story, a story that transcended the normative constraints on a married woman's life.

Thus, the analysis of the communicative events in which Mrs. Lin told, or refrained from telling, the story of her two marriages helps us to appreciate more fully the gravity of the moral dilemma—whether or not to remarry—that she recounted in the narrated event. We can now see that there were lasting consequences of her decision to marry Mr. Wang. As she had hoped, Mr. Wang helped her to secure a future for her children. But those opportunities came at a cost in peace of mind and family harmony: her guilt toward Mr. Wang, her eldest son's rejection of Mr. Wang,

and Mr. Wang's hurt feelings. Perhaps the most poignant consequence was that Mrs. Lin was not able to share with her children the story of her deep love and loyalty to their father.

With this analysis in place, we can now return to the earlier point about private narration. We argue that *A-ma's* eternal bond to her first husband was sustained not only by his dream visitations but also by her private narrations of these visitations and of the events of their brief marriage. The level of detail with which she narrated the most temporally distant of these events to Fung supports this interpretation, implying a great deal of rehearsal. Mrs. Lin may have experienced these internal narratives as a form of private speech to herself and/or as conversations with Mr. Lin, as internal interlocutor. What is certain, however, according to her own testimony, is that the nature of her subjective experience changed during the many years that she abided with him after his premature death. In exactly the same wording each time, *A-ma* repeatedly declared to Fung: "It's not that he occupies my mind [as he did when he first passed away], it's that he actually lives in my mind. Although the person is dead, his soul stays alive." In this astonishing refrain, Mrs. Lin told the ethnographer that her first husband was now alive in her; they had been reunited. Apparently, this transformation in Mrs. Lin's understanding of herself in relation to her husband—from someone who could not stop thinking about him to someone who could not be separated from him—was accomplished through her repeated private narrations.

In summary, although the empirical record is slim when it comes to the narrative practices of older adults, the Western Apache case, and the example of Mrs. Lin suggest that more attention to this phase of life would be worthwhile for cultural psychology. When compared with the narrative practices of young children, the practices of Mrs. Lin and of Western Apache wise men and women are breathtakingly complex. Here are cultural traditions in their most fully realized form, the fruition of a lifetime of repeated practice, in counterpoint to the hints of culture-specific meaning in the stories of young children. These narratives from late adulthood also illustrate the range and diversity of culture-specific subjectivities and social relationships that can be created through decades of narrative practice: wise people with the capacious memory and moral discernment

to repair the social fabric; and a woman who charts an unconventional and largely undisclosed life, and whose marital bond transcends her husband's death.

CONCLUSION

Narrative is a canonical topic in cultural psychology, subsuming many important problems. Our task in this chapter was to address a single, fundamental problem—the role of narrative in the co-creation of person and culture. Drawing upon stories from a variety of cultural traditions, we have argued that practice approaches to narrative can help cultural psychologists to gain purchase on this problem. When narrative is examined as a practice, not just a form of representation, it becomes possible to see how stories reverberate across time and space, connecting people to other people, other stories, and other activities, and infiltrating their hearts and minds.

At both ends of the life course, stories keep happening, just as they do in this chapter. This fundamental characteristic of narrative as an everyday practice endows narrative with constitutive power that goes beyond the capacity of narrative to invoke realities beyond those of the here and now of the telling. Different stories occur in combination with other stories and other activities, and certain stories get repeated like musical themes with variation. All of these practices are saturated with cultural meaning at two levels—how the past event is represented, and how the story is told in the here and now. Regardless of the age of the narrating participants—whether tiny child or older adult—each is helping to keep the practices alive. At the same time, each is getting transformed or retransformed into certain kinds of persons. Because some narrative practices are so frequent and begin so early, it is likely that they become naturalized and taken for granted over the life course, and that the transformations they bring about are beyond the conscious awareness of the participants. Concurrent with this naturalizing trajectory is apparently another trajectory in which participants consciously appropriate shared narrative resources for their own purposes—to manage their emotions, to embark on the journey toward wisdom, or to chart a life path that transcends the conventional terms within which a woman's life could be imagined.

Throughout this chapter we have identified specific questions and phenomena that deserve further inquiry, including the affective–cognitive capacity to become attached to some stories rather than others and the history of stories in people’s lives, ranging from fleeting to lifelong. In conclusion we underscore three methodological implications of practice approaches to narrative. Most research on narrative trains the spotlight on a specific narrative or corpus of narratives, leaving prior, adjacent, or concurrent discursive practices in the shadows. Yet a central premise of practice approaches is that stories do not exist in a vacuum; they coexist with other practices, both narrative and nonnarrative. In their closely observed and provocative study of early narrative practices in a rural African American community, Sperry and Sperry (2000) found that very young children’s precocious facility with fantasy narrative could not be explained by caregivers’ “direct” socialization. Caregivers denied that they encouraged fantasy narratives, and close examination of the fantasy narratives revealed that the children themselves introduced most of the fantasy themes; relatively few were introduced by caregivers. But caregivers did routinely threaten young children with visits from fearsome creatures as a way of socializing right and wrong. Children imported these affectively charged threats and imaginary creatures from prior disciplinary episodes into their narrations. Sperry and Sperry argue that these affectively significant ideas support the production of fantasy much as objects support children’s pretend play. In other words, the very early privileging of fantasy narrations over literal stories—which distinguishes early narrative development in this community—could only be understood by looking beyond narrative itself to examine the conjunction between specific narrative practices and specific disciplinary practices.

In addition to widening the angle of vision beyond narrative to encompass the other practices with which narrative keeps company, practice approaches to narrative invite a closer look at narrative as a multimodal performance (C. Goodwin, 1984; Hanks, 1996; Ochs & Capps, 1996). Van Deusen-Philips et al. (2001) found that linguistically isolated deaf children whose parents chose not to expose them to a conventional sign system produced culturally appropriate narrations despite their lack of a

language model, suggesting that these cultural messages were available through nonverbal channels. They argued that the universality of narrative as a socializing medium rests not only on its capacity for ordering and valuing experience according to many different cultural systems but also on its versatility as a form of enactment. Narrators gesture, adopt postures, display facial expressions, laugh (Jefferson, 1978, 1984), cry (Hill, 1989, 1995), and perform “voices” with more than their mouths. And listeners listen with their eyes and their bodies, not just their ears. It is likely that Yoyo heard *A-ma*’s corrections of his past misdeeds differently when she was holding him in her arms than when she was not. Thus, cultural psychologists who seek to understand the cultural constitution of persons will do well to seek a more balanced approach, one that recognizes that narrative is not only a verbal practice but also a practice of the body.

Finally, and most fundamentally, practice approaches have implications for how researchers position themselves to hear and see narratives in the first place. Each research tool—participant observation, interviews, elicitations—entails some kind of engagement between researcher and participant, and that engagement is part of what has to be documented and analyzed to understand the stories that emerge (or fail to emerge). In other words, the theoretical perspective adopted in this chapter recognizes that the ethnographic encounter is a communicative event, and that findings are intelligible and culturally valid only if the ethnographer is able to adapt his or her research practices to local communicative norms (C. L. Briggs, 1986; Hymes, 1974; Miller, Hengst, & Wang, 2003; Ochs, 1988). Many of the studies cited in this chapter rest on this kind of creative adaptability. But such flexibility is not limited to the ethnographer, as is amply demonstrated by Mrs. Lin. *A-ma* did not accede to the constraints of the researcher-researched relationship or of the initial interview. She appropriated the interview, casting Fung as the recipient of her secret stories and foregrounding Fung’s identity as a certain kind of woman. *A-ma* overlaid the ethnographer encounter with her own purposes. The larger point is this: When the research encounter is regarded as a site in which the ethnographer and participant enter into and reinvent a set of practices, both parties may be surprised by the stories that come to light.

NOTES

1. When Mrs. Lin was young, Taiwan was a colony of Japan (from 1895 to 1945). Although most Taiwanese people spoke *Holo* (also known as *Tai-gi* or Taiwanese) at home, Japanese was the official language used in governmental institutions and schools during that period. When the Kuo-min-tang (KMT; Chinese Nationalist Party) government reclaimed sovereignty over Taiwan in 1945, Japanese was banned. Due to the nostalgic sentiment held by the generation of Taiwanese who grew up in the colonial period, Japanese somehow gradually changed from a generally public language to a language of affection and emotion in private communication. Thus, one possible explanation why Mrs. Lin vowed to her deceased husband in Japanese could be that she experienced Japanese to be more appropriate than *Holo*, her native tongue, for expressing the intensity of her inner feelings for him.

2. It is interesting that Mrs. Lin regarded her first husband's dream visitations so positively. An alternative interpretation might be that Mr. Lin's dream visitations were acts of surveillance, signifying his disapproval of her second marriage. Such an interpretation would be compatible with Mrs. Lin's own strong wish not to remarry. Unfortunately, we have no way of knowing how she interpreted Mr. Lin's dream visitations when they first occurred many years earlier, or whether her interpretations changed over time, culminating in her conviction late in life that Mr. Lin's dream visitations signified his continuing love and support for her.

CHAPTER 25

Culture, Categorization, and Reasoning

DOUGLAS L. MEDIN
SARA J. UNSWORTH
LAWRENCE HIRSCHFELD

Do people from different cultures have different categories and concepts? What aspects of the way a person thinks depend on the culture in which one grew up? In this chapter we review research on concepts and reasoning from a cultural perspective. It is tempting to plunge right into the literature, without saying much about the notion of culture itself, because, as many people believe, everyone has a pretty good idea about what culture is. To the contrary, we believe that a great deal hinges on how one conceptualizes culture, including challenging methodological and interpretive issues, and deep commitments to research strategies. Therefore, we plunge right away into different approaches to studying culture.

What is at stake is not so much determining which approaches to culture are correct and which are incorrect but rather what their strengths and weaknesses might be relative to the questions and issues one would like to address. First, there is an issue on which everyone who studies culture can agree. Given that much of the history of cognitive and social psychology has focused nearly exclusively on college students at major research universities, we really need to know the generalizability of these findings. Both the presence and absence of gen-

erality are informative. We think that *the* scandal of cognitive and social psychology is its narrow empirical base—it reflects either immense optimism with respect to universality or is too pessimistic about being taken seriously. In short, psychology needs cultural research to be legitimate.

The challenges arise when cultural differences are observed. Aside from jarring us out of our complacency, what more can we say? A central problem is that culture is not an independent variable, and cultural comparisons provide very little by way of experimental control. This is where different approaches to culture part company, strategically speaking. We now take a closer look, starting with intuitive approaches to culture.

APPROACHES TO STUDYING CULTURE

We begin with an important distinction: The question of how cultures should be studied is separable from the question of how to define cultures. Intuitively, one might define “culture” as the shared knowledge, values, beliefs, and practices among a group of people, typically living in geographical proximity, who share a

history, a language, and cultural identification. Although we think a definition of a culture in terms of history, proximity, language, and identification is useful and (if not too rigidly applied) perhaps even necessary, it does not follow that the cultural content of interest must be shared ideas and beliefs.

We see three problems with the intuitive view of culture and its focus on shared content. First, it prejudices the issue of what constitutes cultural content. If culture is shared and we encounter a tradition in which a diversity of ideas, values, and practices compete, are we to conclude that the tradition is not cultural because it is not consensual? Second, this view of culture is static, in that either cultural change is not a relevant object of study or is treated as (cultural) loss, or in some cases, extinction. Third, this approach may implicitly essentialize culture by conceptualizing it as an entity with systematic, law-like properties.

In this section we look at a number of approaches that in different ways endorse or reject this agenda for cultural research.

Culture as Norms and Rules

It is very natural to think that the cultural contents of interest must be shared to qualify as "cultural." Note, however, that this commitment undercuts the dynamic side of cultural processes. There might well be distinctive values, beliefs, and knowledge within a culture that nonetheless are not consensual. For example, a culture may have a set of beliefs and practices known only to a privileged group of people (e.g., healers, elders, ruling elite).

Some influential models of culture formation and evolution in biology and anthropology take a somewhat more liberal view of consensus. Based on group-level traits, they assume that cultures are integrated systems consisting of widely shared social "norms" ("rules," "theories," "grammars," "codes," "systems," "models," "worldviews," etc.) that maintain inheritable variation (Rappaport, 1999; Laland, Olding-Smee, & Feldman, 2000; Wilson, 2002). Some political scientists also tend to view cultures as socially "inherited habits" (Fukuyama, 1995), that is, as socially transmitted bundles of normative traits (Huntington, 1996; Axelrod, 1997).

The interest in inheritable variation loosens the restrictions on consensus and raises questions about the basis for variation. But here

cognitive scientists are likely to be disappointed by the implicit assumption that the gist of cultural learning is the (automatic) absorption of norms and values from the surrounding culture (by processes no more complicated than imitation). We believe that these assumptions do not pay sufficient attention to the sorts of inferential and developmental cognitive processes that allow human beings to build and participate in cultural life.

Cultural Psychology

Studies in the area of "cultural psychology" have made important contributions to human understanding by showing that knowledge systems and associated ways of thinking previously assumed to be universal actually vary widely across the world (for a review, see Cohen, 2001). The lesson drawn is that "psychologists who choose not to do cross-cultural psychology may have chosen to be ethnographers instead" (Nisbett, Peng, Choi, & Norenzayan, 2001, p. 307). In brief, cultural psychology is succeeding in divesting academic psychology of implicit and ingrained ethnocentric biases.

Cultural psychology differs from the "norms and rules" approach in at least two distinct ways: (1) Cultural psychology has tended to focus on reducing cultural differences to differences in values along a small set of dimensions; and (2) cultural psychologists have claimed that these differences also mediate differences in cognitive processes. In short, culture affects not only what people think about but also how they think.

The area draws much of its inspiration from researchers such as Hofstede (1980) and Triandis (1995), who sought to characterize cultural differences in terms of a small number of relevant dimensions. The project is successful if converging evidence points to the same small set of dimensions. Examples of such dimensions that have received a lot of attention are individualism versus collectivism and egalitarian versus hierarchical social structure. Other researchers, such as Nisbett (2003), have used socio-historical analysis to analytically derive differences in worldviews or preferred modes of thought. Examples of these differences are analytic versus holistic and logic versus dialecticism. In short, Nisbett and his associates (2001) are suggesting that what they call cultural studies must include not only contents *per se* but also thinking processes that them-

selves may be differentially distributed across cultures.

The recent interest in cultural psychology (for a review and critique, see Oyserman et al., 2002, and associated commentaries) has produced a considerable array of intriguing findings. In our view, however, the field risks being inherently self-limiting, because it tends to focus on very abstract, superordinate-level contrasts. It is difficult to argue with success, but it is equally difficult to overcome the impression that the picture is somewhat oversimplified. Here is an analogy. Suppose we were trying to understand the object concepts associated with a language and culture. It would be possible to take a large sample of such concepts, develop some measure of similarity, and then do multi-dimensional scaling (MDS). We would probably be able to recover meaningful dimensions of similarity such as size, animacy, and affective valence. But knowing object concepts as we do, we would likely have the feeling that a great deal was missing. In the 1950s Osgood, Suci, and Tannenbaum (1957) undertook a project of this sort (using the so-called “semantic differential technique”) and uncovered several abstract dimensions, such as valence (pleasantness vs. unpleasantness) and potency (active vs. passive). Although dimensions such as positive versus negative evaluation have been of some use in subsequent research (Niedenthal, Halberstadt, & Innes-Ker, 1999), no one would mistake this dimensional analysis with a theory of semantics and overall, the MDS approach has fallen into neglect.

A second limitation of cultural psychology is that when a hypothesized cultural difference is reported, it is not clear how explanation or interpretation can be extended beyond simple description. In some cases researchers have been able to exert some experimental control by priming tendencies to act individualistically versus collectively (e.g., Gardner, Gabriel, & Lee, 1999; Briley, Morris, & Simonson, 2000). These sorts of studies reinforce the dimensional analysis and potentially extend its scope (Oyserman & Lee, Chapter 10, this volume). There is always the risk, however, of circularity in analysis. If priming does not affect some candidate task measuring individualism versus collectivism, then perhaps the prime is ineffective or the task does not entail individualism and collectivism.

Perhaps we are guilty of prejudging the initial phase of a two-step project. A focus on

within-culture variations in modes of thought might illuminate how different cultural institutions shape ways of thinking and vice versa (see Kitayama, Duffy, & Uchida, Chapter 6, this volume; Kitayama, Ishii, Imada, Takemura, & Ramaswamy, 2006).

Context and Situated Cognition

Alternative views of “cultural psychology” call into question the use of standard forms of experimental procedure as flawed on the grounds that they are biased in their focus on the individual mind/brain in isolation. Instead of considering cognitions to be embedded exclusively in individual minds, with “culture” as just one component of individual cognition, these theorists maintain that human cognitions should be properly situated in a cultural–historical context and “practical activity” (Cole, 1996; cf. Vygotsky, 1978). A related concern is that cultural cognitions may be better understood as “distributed cognitions” that cannot be described exclusively in terms of individual thought processes, but only as “emergent structures” that arise from irreducible levels of interactional complexity involving differential linking of individual minds in a given population (Hutchins, 1995). Cole (1996) argues that subjects and objects are not only directly connected but also indirectly connected through a medium comprising artifacts, which are simultaneously material and conceptual. One consequence of this view is an emphasis on studying cognition in context, where cognitive labor may be distributed across both individuals and artifacts (e.g., plumb lines or computers). Because context includes people’s conceptions of artifacts, it is inherently relational.

We share some of these concerns raised by the situated view, such as difficulties with standard experimental procedures, including 2×2 designs with culture, in effect, treated as an independent variable (Atran, Medin, & Ross, 2005) and lack of concern with differential distributions of cognitions among minds within populations. We also agree that cultural notions are intimately tied to the study of development, and that one excellent research avenue involves looking at how cognition plays out in particular contexts.

But we find other aspects of the situated view somewhat problematic. First, it is not always clear when a proposal is to be read as a metaphor and when it is to be taken literally,

for example, the idea that cognition is “distributed” or even “stretched across mind, body, activity and setting” (Lave, 1988, p. 1). The focus on practical activity can be very useful, but to make activity the primary, or in some cases the sole unit of analysis, is to ignore individual cognitions.

The situated view and cultural psychology represent two end points on a continuum of scope and specificity. Cultural psychology aims to identify a small set of cognitive processes that (are thought to) operate very widely. In contrast, situationists are more impressed with the lack of transfer of cognitive skills across settings (e.g., Lave, 1988). The final view we discuss falls in the middle of this continuum.

Cultural Epidemiology

We endorse looking at cultures in terms of mental representations (and attendant behaviors) that are distributed across individuals in a population—what Sperber and others have called “cultural epidemiology.”¹ This view focuses on the stabilizing role of cognitive structures in production and transmission of ideas (and attendant behaviors) that achieve widespread cultural distribution. These are not exclusively or even mainly shared as nearly identical mental representations across individual minds (Atran, 2001; Sperber, 1996). For example, imitation has strong limits: Given the multiple mappings between acts and mental representations of them (including their meaning), there is no guarantee of any sort of fidelity. Rather, much of the cultural transmission and stabilization of ideas (artifacts and behaviors) involves the communication of fragmentary bits of information that manage to trigger prior, rich inferential structures (Sperber & Hirschfeld, 2004).

We see two main limitations of the distributional view of culture: (1) Its focus on ideas may not give appropriate weight to the role of institutions, artifacts, and contexts; and (2) the notion of “idea” is underspecified in much the same way that the notion of a feature is underspecified in models of similarity (Murphy & Medin, 1985). Both limitations reflect the fact that the distributional view is stated at a fairly abstract level, so they are probably the same symptom. For instance, in an attempt to concretize the notion of “idea,” one will likely find that ideas are not only influenced by institutions, artifacts, and contexts but also include

key features of these phenomena in their representational makeup.

At the same time, the distributed view of culture has several important strengths. First, it directs attention to within-culture variation and processes of cultural transmission. Second, cultural differences are a beginning point for analyses, not an end point. Third, this view requires that cultural consensus be empirically demonstrated rather than simply presumed. Consequently, cultures are seen as a dynamic system in which different perspectives and ideas may be in competition. All of these factors are relevant to the methodological considerations to which we turn next.

METHODOLOGY FOR CULTURAL RESEARCH

It is our view that cultures can be effectively studied as causally distributed patterns of mental representations, their public expressions, and the resultant behaviors in given ecological contexts. We say “distributed” to emphasize that the distribution of ideas may be highly variable, and “causally” to make the point that whether and how representations are formed, transmitted, or transformed depends on particular contexts, as we elaborate below. People’s mental representations interact with other people’s mental representations to the extent that those representations can be physically transmitted in a public medium (language, dance, signs, artifacts, etc.). These public representations in turn are sequenced and channeled by ecological features of the external environment (including the social environment) that constrain psychophysical interactions between individuals (Sperber, 1996).

A significant departure from a culture as “shared norms and rules” perspective is that the variable distribution of ideas, which are themselves objects of study, and disagreement across observers, is treated as signal, not as noise. The distribution view avoids the limitations of considering “culture” a well-bounded system or cluster of practices and beliefs (see Brumann, 1999, and commentaries for examples), in favor of using a set of techniques for assessing groupwide patterns that statistically demonstrate cultural consensus or lack thereof. This proposal has the advantage that it avoids trying to define culture, focusing attention instead on the distribution of cultural representations.

In our work we have relied extensively on the cultural consensus model (CCM) of Romney, Weller, and Batchelder (1986), an important tool for analyzing commonalities and differences within and across cultural groups. The CCM has been an effective tool for cognitive anthropologists (e.g., Moore, Romney, Hsia, & Rush, 2000; Romney & Batchelder, 1999; Romney, Brewer, & Batchelder, 1996). Consensus modeling permits recovery of graded patterns of variation within and between populations (down to the level of the individual and up to the level of combining cultural patterns to show “metacultural” interaction and consensus). Rather than locating “cultural analysis” at any one level, one can explore the existence of agreement patterns, linking them to environmental (social and physical) processes and phenomena.

Other researchers (e.g., Eid & Diener, 2001) have employed latent class analysis to identify subgroups. A limitation of latent class analysis not shared by the CCM is that fairly large sample sizes are needed to identify subgroups.

Accordingly, it is less useful to try to estimate population parameters for such norms and associated behaviors (especially when cultural studies consist of cross-national samples of college students) than to establish the pathways that determine how ideas (in our case, categories and concepts) affect reasoning and behaviors. For example, in some of our work we have identified cultural differences in approaches to nature but then have been able to link within-group variation in mental models with corresponding within-group variation in cross-group stereotyping (Medin, Ross, Cox, & Atran, 2006). This means that trying to establish a truly random sample may be much less useful than selecting a sample that is most likely to reveal some cultural processes of interest (this contrasting strategy is known as *purposive sampling*).

The Cultural Consensus Model

The CCM assumes that widely shared information is reflected by a high concordance among individuals. Estimation of individual competencies is derived from the pattern of interinformant agreement on the first factor of a principal component analysis (essentially factor analysis). A cultural consensus is found to the extent that the data overall conform to a single factor solution (the first latent root is

large in relation to all other latent roots), and individual scores on the first factor are strongly positive. These competency scores should not be mistaken for scores of expertise. The cultural model provides a measure for culturally shared knowledge; hence, the levels of competencies measure the extent to which an individual shares what everyone else agrees upon. The CCM is not a theory of culture or of the cultural transmission of information, any more than analysis of variance is a theory of cognition. It is only a tool that can be used to evaluate such theories.

Of course, general agreement may be coupled with systematic disagreement, and the CCM is an effective tool for uncovering both shared and unshared knowledge. After the consensus parameters are estimated for each individual, the expected agreement between each pair of informants is generated (as the product of their respective consensus parameters). Next, the expected agreement matrix is subtracted from the raw agreement matrix to yield a matrix of deviations from expected agreement (cf. Hubert & Golledge, 1981). If raw and residual agreement are significantly associated, then a significant portion of residual agreement consists of deviations from the consensus. One can then explore other factors (e.g., cultural subgroups, social network distance) that might predict or explain the residual agreement. For example, Medin, Lynch, Coley, and Atran (1997) asked tree experts to sort local species of trees into groups and found a clear overall consensus, coupled with reliable residual agreement. They then examined second-factor scores and found that they correlated strongly with occupation (e.g., parks maintenance worker, taxonomist, landscaper). Subsequent comparisons revealed systematic differences in the basis for sorting across groups.

Logic and Strategy in Cross-Cultural Comparison

One reason that comparative research has been unpopular is that it is not always clear how to do it successfully. When one compares two groups and finds clear differences, interpretive problems quickly emerge. Which of the many ways in which the two groups differ are crucial? For example, López, Atran, Coley, Medin, and Smith (1997) found that U.S. undergraduates and Itza' Maya of Guatemala showed different patterns of responding on a category-

based inductive reasoning task involving mammals. Although this undermines the universality of the particular reasoning phenomenon, the two groups differed in myriad ways (age, education, literacy, livelihood, language, cosmology, etc.). Which of these differences matters? Practically speaking, it may be impossible to disentangle these various factors. Suppose we could control for age, education, literacy, and the like in comparing Itza' Maya and undergraduates. How do we decide which variables represent "culture" and should therefore not be controlled, and which variables do not, and should be controlled? The Itza' Maya practice agroforestry and also hunt and collect plants in the forest. Should these factors be controlled or are they part of Maya culture?

Now suppose that we control for every variable we can think of and still find differences. In this case, it seems that one is more or less forced to reify or essentialize culture; that is, the only explanation of the cultural difference involves appealing to some abstract notion of "culture." In short, it seems that we may be caught between two equally undesirable possibilities: (1) to end up with a notion of culture that solely has recourse to circular explanations of differences ("The Itza' are different because they are Itza' "); (2) to conclude that cultural comparisons just represent confounded experiments, and the notion of culture is not needed once proper experimental control is achieved.

Triangulation as a Research Strategy

There is no theoretically neutral way to define culture (see Atran et al., 2005). We have just suggested that the idea that culture is whatever is left when all potentially confounding variables are controlled is self-defeating. Granted, it is useful to control for variables that are clearly irrelevant to culture. But one must bear in mind that decisions about what is irrelevant are necessarily theory-based and commit one to a particular notion of culture.

Because (cultural) groups cannot be found that represent orthogonal combinations of variables, it may be impossible in principle to disentangle the various sources of variation among groups. The general idea of triangulation is to use observations from a third group to get at least modest leverage for understanding initial group differences. The third group should resemble the first group in some poten-

tially important ways and the second group in other ways. If the third group performs like one of the groups and differently from the other group, then the variables shared by the third group and the group it mimics become candidates for critical variables.

To illustrate this strategy, consider again the findings of López et al. (1997). In that study, we compared Itza' Maya elders and University of Michigan undergraduates on categorization and reasoning involving local mammals (local to Petén and to Guatemala and Michigan, respectively). We told informants of a new disease that we know affects *coyotes* and *wolves*, and another new disease that affects *coyotes* and *cows*. Then we asked which disease is more likely to affect all mammals.

University of Michigan undergraduates overwhelmingly said the disease that coyotes and cows get is more likely to affect all mammals. They justified their answers by appealing to the dissimilarity of the two premises, or *diversity*; that is, they said that if some disease affects mammals as different as coyotes and cows, it is likely to affect all mammals. This reasoning strategy seems straightforward, and the Osherson, Smith, Wilkie, Lopez, and Shafir (1990) model for category-based reasoning predicts that people will prefer more diverse premises in drawing inductions to a category. What is surprising is that the Itza' Maya did not show a diversity effect. In some cases they were reliably *below* chance in picking the more diverse premises on these kinds of tests.

Why did the Itza' not use a diversity-based reasoning strategy? Obviously, there are any number of hypotheses one could conjure up. Perhaps the question was not asked quite the same way in Itza' Maya (back translation is no guarantee of equivalence), or perhaps formal education is a prerequisite for this form of abstract thought, or perhaps the Itza' have a very different conceptualization of disease. The answer just is not clear.

Here is where our triangulation strategy proved to be effective. In this case, the third group was U.S. tree experts who were asked to reason about novel tree diseases. They resembled both the Michigan undergraduates in many respects (language, formal education, etc.) and the Itza' with respect to having considerable domain knowledge. A typical diversity probe might be as follows: "White pine and weeping willows get one new disease and river birch and paper birch get another. Which

is more likely to affect all trees?” Using these kinds of probes, Proffitt, Coley, and Medin (2000) found that parks workers, like the Itza’, showed reliably below chance diversity responding. As we elaborate later, both groups were employing a reasoning strategy that is sensible and coherent—it just does not show up in undergraduate reasoning, for reasons that we will soon make clear. For now, we simply note that the triangulation strategy pinpoints domain knowledge as a key variable in diversity responding (though, as we will see, this is not the whole story).

At first glance, it might appear that the triangulation strategy is just a 2×2 design with one cell missing. In our example, one factor might be *cultural group* and the other, *expertise*, with the missing cell being the Itza’ Maya, who lack knowledge of biological kinds. But a 2×2 design presumes what the triangulation strategy is intended to discover, namely, which factors are crucial to group differences. So, in our case, *expertise* seems to be the main factor and the factor of *culture* is just a stand-in for the many ways the groups might differ, which may or may not be relevant for some specific task. The logic of triangulation implies compression of any number of possible 2×2 designs that together entail a host of possible explanations for group differences. Instead of 2^N controlled designs, each of which allows inference to a single factor, a carefully chosen third group deliberately confounds a number of variables. By carefully choosing a third group, C, that resembles both the first group, A, in a number of ways and the second group, B, in a number of other ways, one can assess the relative importance of the set of culturally confounded variables by which C differs from A versus C differs from B.

OVERVIEW OF CONCEPTS AND CATEGORIES

It is not easy to organize this review, because (mainstream) psychology has a different history and perspective than anthropology. Our compromise is to come at it both ways, noting the frequent parallels. We begin our overview with theories of concepts and categories that have arisen out of mainstream cognitive psychology, which has been more concerned with mental representations and abstract structural properties of categories than has anthropology. We then review research emanating from both anthropology and psychology that has investi-

gated concepts and categorization across cultures.

In what follows, we use *concept* to refer to a mental representation, and *category* to refer to the set of entities or examples picked out by the concept. It is generally accepted that instances of a concept are organized into categories (Smith & Medin, 1981). Almost all theories about the structure of categories assume that, roughly speaking, similar things tend to belong to the same category and dissimilar things tend to be in different categories. For example, robins and sparrows both belong to the category *bird* and are more similar to each other than they are to squirrels or pumpkins. “Similarity” is a pretty vague term, but it is most commonly defined in terms of shared properties or attributes. Although alternative theories assume that concepts are structured in terms of shared properties, theories differ greatly in their organizational principles. The *classical view* assumes that concepts have defining features that act like criteria or rules for determining category membership. For example, a triangle is a closed geometric, three-sided form, with the sum of the interior angles equaling 180° . Each of these properties is necessary for an entity to be a triangle, and these properties together are sufficient to define a “triangle.”

A fair amount of research has examined people’s knowledge about object categories such as *bird*, *chair*, and *furniture*, and this evidence goes against the classical view. People not only fail to come up with defining features but also they do not necessarily agree with each other (or even with themselves when asked at different times) on whether something is an example of a category (Bellezza, 1984; McCloskey & Glucksberg, 1978). Philosophers and scientists also have worried about whether naturally occurring things such as plants and animals (so-called “natural kinds”) have defining features. The current consensus is that most natural concepts do not fit the classical view.

The major alternative to the classical view, the *probabilistic view* (see Smith & Medin, 1981), argues that concepts are organized around properties that are characteristic or typical of category members, but, crucially, they need not be true of all members; that is, the features are only *probable*. For example, most people’s concept of bird may include the properties of building nests, flying, and having hollow bones, even though not all birds have these properties (e.g., ostriches, penguins). The

probabilistic view has major implications for how we think about categories. First, if categories are organized around characteristic properties, some members may have more of these properties than other members. In this sense, some members may be better examples or more typical of a concept than others. For example, Rosch and Mervis (1975) found that the more frequently a category member's properties appeared within a category, the higher its rated *typicality* for that category. For instance, robins were rated to be very typical birds and penguins were rated as very atypical birds. A second implication is that category boundaries may be fuzzy. Nonmembers of a category may have almost as many characteristic properties of a category as do certain members. For example, whales have a lot of the characteristic properties of fish, yet they are mammals. Third, learning about a category cannot be equated with determining its defining features, because there may not be any (see, Murphy, 2002, for a general review).

Is typicality based only on central tendency? Although typicality effects are robust (and problematic for the classical view), other research shows that the underlying basis for typicality effects may vary with both the kind of category and the population being studied. Barsalou (1985) reported that the internal structure of taxonomic categories is based primarily on the central tendency (or the average member) of a category. In contrast, the internal structure of goal-derived categories, such as "things to wear in the snow," is determined by some ideal (or the best possible member) associated with the category. The best example of snow clothing, a down jacket, was not the example most like other category members; instead it was the example with the maximum value of the goal-related dimension of providing warmth.

One might think that ideals will only come into play when the category of interest lacks the natural similarity structure that characterizes common taxonomic categories, such as *bird*, *fish*, and *tree*. However, recent evidence undermines this idea. Lynch, Coley, and Medin (2000) found that, for tree experts (people who know a lot about trees, e.g., landscapers, parks workers and taxonomists), the internal structure of the category *tree* was organized around the positive ideal of height and the negative ideal of weediness. The best examples of *tree* were not trees of average height but trees of extraordinary height (and free of "weedy" char-

acteristics, e.g., having weak limbs, growing where they are not wanted, and being susceptible to disease).

Other research is consistent with the idea that people who have considerable knowledge in a domain tend to base typicality judgments on ideals, and not on the number of typical features (Johnson, 2001). For instance, for Itza' Maya adults living in the rain forests of Guatemala the best example of bird is the wild turkey, which is culturally significant, prized for its meat, and strikingly beautiful (Bailenson, Shum, Atran, Medin, & Coley, 2002). The Lynch et al. (2000) finding that U.S. tree experts based typicality on ideals suggests that it is not just that the Itza' have a different notion of what typicality means. Burnett, Medin, Ross, and Blok (2005) also found that Native American and European American fishermen's typicality judgments were based on ideals, though those ideals differed somewhat across groups.

If categories are not represented in terms of definitions, what form do our mental representations take? One suggestion about how concepts are represented is known as the "family resemblance principle." The general idea is that category members resemble each other in the way that family members do. A simple summary representation for such a family resemblance structure would be an example that possessed all the characteristic features of a category. The best example is referred to as the *prototype*.

In a prototype model of categorization, a new example is classified by comparing the new item to the prototype. If the candidate example is similar enough to the prototype for a category, it is classified as a member of that category. More detailed analyses, however, show problems with prototypes as mental representations. Prototype theory implies that the only information abstracted from categories is the central tendency. A prototype representation discards information concerning category size, the variability of the examples, and correlations among attributes. The evidence suggests that people can use all three of these types of information (Estes, 1986; Flannagan, Fried, & Holyoak, 1986; Fried & Holyoak, 1984; Medin, Altom, Edelson, & Freko, 1982).

An alternative approach, which is also consistent with the probabilistic view, assumes that much more information about specific examples is preserved. This approach appropriately falls under the general heading of *exemplar*

theories. Exemplar models assume that people initially learn some examples of different concepts, then classify a new instance on the basis of how similar it is to the previously learned examples. The idea is that a new example reminds the person of similar, old examples and he or she assumes that similar items will belong to the same category. For example, suppose you are asked whether large birds are more or less likely to fly than small birds. You probably will answer “less likely,” based on retrieving examples from memory and noting that the only nonflying birds you can think of are large (e.g., penguin, ostrich).

Quite a few experiments have contrasted the predictions of exemplar and prototype models. In head-to-head competition, exemplar models have been substantially more successful than prototype models (see Estes, 1994; Lamberts, 1995; Medin & Coley, 1998; Nosofsky, 1992; Nosofsky & Palmeri, 1997; Storms, De Boeck, & Ruts, 2000; Verbeeman, Vanoverberghe, Storms, & Ruts, 2001; Smits, Storms, Rosseel, & De Boeck, 2002; but for opposing views see Homa, 1984; Smith & Minda, 1998, 2000).

Why should exemplar models fare better than prototype models? One of the main functions of classification is to allow one to make inferences and predictions on the basis of partial information (see Anderson, 1990a, 1990b). Relative to prototype models, exemplar models tend to be conservative about discarding information that facilitates predictions. For instance, sensitivity to correlations of properties within a category enables finer predictions: From noting that a bird is large, one can predict that it cannot sing. In short, exemplar models support predictions and inferences better than do prototype models.

A number of researchers have argued that the organization of concepts is knowledge-based (rather than similarity-based) and driven by intuitive theories about the world (for a general review, see Carey, 1985; Keil, 1989; Murphy & Medin, 1985; Murphy, 2002). The idea that concepts might be knowledge- rather than similarity-based suggests a natural way in which concepts may change, namely, through the addition of new knowledge and theoretical principles. There is also good evidence that these theories help determine that abstract and observable features to which learners pay attention (Spalding & Ross, 2000; Wisniewski & Medin, 1994). The set of categories for mental disorders now differs from that 100 years ago,

in part because our knowledge base has become more refined. Often knowledge of diseases develops from information about patterns of symptoms to a specification of underlying causes. For example, the advanced stages of syphilis were treated as a mental disorder until the causes and consequences of this venereal disease were better understood. Kim and Ahn (2002) have shown that clinical psychologists organize their knowledge of mental disorders in terms of the rich causal theories (and not the atheoretical diagnostic manual they are supposed to use) that guide their diagnostic classification and reasoning.

FOLK BIOLOGY AND NATURAL KINDS ACROSS CULTURES

Perhaps one of the most natural questions to ask about concepts is whether people in different cultures have different ones. Concepts are the building blocks of thought, and at the heart of this question is whether people in different cultures think differently. Usually this question is tied up with the question of whether and how language influences thought (see Gentner & Goldin-Meadow, 2003, for a series of reviews and comments on this issue, which we do not cover separately here). Of course, if thought processes of two cultural groups were radically incommensurable, one would quickly realize there dramatic differences but be at something of a loss to explain them. The fact that one part of learning a foreign language involves finding out what term or word is used to refer to *bird*, *fish*, *chair*, *Tuesday*, or *mother* suggests that comparable concepts and categories are in play.

Folkbiology

Research in the domain of living kinds has allowed a natural comparison of concepts across cultures. Perhaps the most striking result is the strong cross-cultural agreement in categorizing plants and animals. Consider an ethnobiologist undertaking the study of folkbiology in some new culture. The project could hardly get under way before he or she asks what living kinds are found in that culture, what terms exist in the language referring to living kinds, and what the relation is between those terms and what is there (the issue of reference). How does one describe what living kinds exist in some cultural context? A reasonable starting point is

to use scientific taxonomy as a reference or standard. For example, one might ask whether every kind that science recognizes as a distinct species has a distinct name (Diamond & Bishop, 1999). Upon finding that many kinds do not have distinct names, it is natural for one to ask what principles determine whether or not a species has a distinct name (Berlin, 1992). For example, naming could be driven by relevance to humans (utility), perceptual discontinuities, or even size (Hunn, 1999).

Scientific taxonomy is, of course, a hierarchical taxonomy and, as such, provides both a standard and a heuristic for asking other questions about universal aspects of folktaxonomies. Two important analytic points are involved here: First, although the particular kinds of plants and animals to be found may vary across cultures, the abstract structure in terms of species, genus, family, order, class, division, and kingdom will be represented. Consequently, scientific taxonomy provides something of a conceptual grid for cross-cultural comparisons. The second, related point is that scientific taxonomy allows one to establish corresponding ranks, such that it becomes meaningful to state that *oak* is at the same level or rank as *trout*. This does not mean that they are psychologically at the same rank, but it does provide a basis for asking questions, such as whether some culture differentiates mammals more than fish. As it turns out, ethnobiologists have found that folk ranks and folktaxonomies only roughly approximate scientific taxonomies (Hunn, 1975). By *roughly*, we mean that the correlation between scientific taxonomic distance of species (i.e., the number of nodes that must be traversed to connect species *x* and species *y*) and folktaxonomic distance is about .75. On the one hand, this may be seen as quite high but on the other, this accounts for only about 50% of the variance.

Folkbiology is a field blessed with many intriguing and important issues that lend themselves to an analysis in terms of culture and cognition. Let us turn to a few of them.

Are Folkbiological Categories Recognized or Constructed?: Egghead versus Utilitarian Perspectives

A basic issue within ethnobiology concerns whether categories are recognized or constructed (see Malt, 1995; Brown, 1995). One view—known within ethnobiology as the “intellectualist view”—is that the structure of

kinds in nature comprises “chunks” that more or less impose themselves on minds (at least on minds with a perceptual system like ours). This position is reinforced by the finding that folk categories often correspond to scientific species or genera and by quite strong cross-cultural agreement in folktaxonomic systems (e.g., Atran, 1990; Berlin, 1992; though Atran interprets agreement in terms of universal properties of mind rather than the structure of nature alone).

The alternative, or “utilitarian,” view is that folktaxonomic systems are influenced by goals, theories, and belief systems, and that they may be culture-dependent constructions (Hunn, 1982; Ellen, 1993). For instance, Hunn (1982) noted that the Tzeltal peoples do not differentiate as finely among butterflies as they do among butterfly larvae, because the larvae are important for food and are also crop pests. Berlin (1978) found that Aguaruna and Tzeltal peoples formed generic categories for plants that were of no utility to them, yet further division into more specific categories was made for plants that were considered useful. In short, the role of utility seems to vary with taxonomic rank. The intellectualist view appears to be fairly accurate at the rank of folk generics (e.g., dog, pine, trout), and the utilitarian view holds more sway at the level of folk species (e.g., poodle, white pine, brook trout) and variety (e.g., toy poodle, Western white pine).

Other, intermediate positions hold that the intellectualist and utilitarian views are not necessarily mutually exclusive. For example, their relative influence may depend on factors such as rank in the hierarchy (Bulmer, 1970): Cultures may differ more in the structure and use of categories such as *tree* or *bird* (corresponding roughly to class in scientific taxonomy) than they do for *oak* or *robin* (corresponding roughly to the generic or species level).

A final twist on this issue arises from studies that have included informants from groups with less intimate contact with nature. Consider the research conducted by López et al. (1997). When comparing folkbiological taxonomies, López et al. found that Americans and Itza' were more or less equally competent in their classification of mammals, as judged by the correlation between sorting distance and formal taxonomic distance. Furthermore, classification in both groups was largely based on the morphology and behaviors of the mammals. However, relative to the American undergraduates, the Itza' were more likely to differ-

entiate among smaller mammals, were less likely to group mammals together in large groups, gave greater weight to ecological considerations, and gave less weight to size and domesticity. Indeed, for the undergraduates, most of the variance in sorting could be accounted for on the basis of size alone. In other words the undergraduates had a somewhat impoverished knowledge of mammals relative to that of the Itza'.

In related work, Bailenson et al. (2002) asked U.S. experts, U.S. novices (college students) and Itza' Maya to sort pictures of U.S. and Guatemalan birds into groups. They found that the Itza' sorting correlation with scientific taxonomy for U.S. birds was actually higher than the correlation of the U.S. novice sorting for U.S. birds, again suggesting that the U.S. college students had somewhat impoverished knowledge of birds (for more data and discussion of the cognitive consequences of impoverished contact with the biological world, see Johnson & Mervis, 1998; Medin & Atran, 2004).

Does Nature Have Joins?

THE BASIC LEVEL

An important observation about categories is that people are not confused about which label to use when asked about an object. For example, a person looking at a four-legged furry animal that had just fetched a ball would more likely call it a *dog* than an *animal* or a *poodle*. This intermediate level of abstraction, which seems to provide the label that we would use as a default, is called the *basic level*, and it appears to be especially salient and psychologically privileged. For example, basic-level concepts are the first to be learned, the natural level at which objects are named, and the highest level in which the instances all share the same parts and overall shape (Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976). The basic level resides at a middle level of abstraction. More abstract categories (e.g., animal) are called *superordinates*, and more specific categories (e.g., golden retriever) are called *subordinates*. Berlin (1992) found that among traditional societies, the basic level for plant and animal categories seems to correspond to the folk-generic level (e.g., *maple*, *trout*). Berlin calls these categories "beacons on the landscape of biological reality" (p. 53). Consistent with this claim, the genus level is the rank

where cross-cultural agreement in categorization is maximized.

Although traditional ethnobiological studies point to the folk-generic level as privileged, Rosch et al. (1976) found that for American undergraduates, the basic level seemed to correspond to the more abstract life-form level (e.g., *tree*, *fish*). One way of reconciling these two claims is to again argue that American undergraduates do not have the requisite experience with biological kinds to develop what would otherwise be a universal appreciation of the genus level. Some cross-cultural studies have directly addressed this issue.

Coley, Medin, and Atran (1997) have examined whether the cultural differences in the privileged or basic level in taxonomic classification correspond to cultural differences in the privileged level for folkbiological induction. A level is defined as privileged if inferences to this level are significantly stronger than inferences to the immediate superordinate level, but no stronger than inferences to a subordinate level (if there is a subordinate level). The former task may measure consequences of experience, and the latter may assess expectations rather than knowledge about categories. Coley et al. told American undergraduates and the Itza' elders that an unfamiliar property was characteristic of all members of a particular category, and asked how likely this was to be true of members of a more general category. If the basic level is the level above which information is lost, and below which little information is gained (Rosch et al., 1976), then the privileged level for induction should be the basic level. Based on Berlin's (1992) and Rosch et al.'s (1976) research, Coley et al. (1997) predicted that the privileged level for induction should be the folk-generic level for the Itza' and the life-form level for the American undergraduates.

Coley et al. (1997) found that the privileged level for inductive inferences was the folk-generic level for both groups of participants; that is, the strongest inductions were made from the folk-generic level to the life-form level, relative to all other inductions. Thus, there is a dissociation of knowledge and expectations in Americans' folkbiological categories. In spite of the fact that undergraduates may have little specific knowledge about the sparrow, trout, or oak, expectations about the informativeness of categories serve to maximize inductive inferences at the folk-generic taxonomic level. Indeed, Coley, Hayes, Lawson, and Maloney (2004) found that for living

kinds, inductions are influenced more by expected informativeness (measured by collecting ratings of perceived similarity among category members at different levels) than by specific knowledge of the concepts themselves (measured by asking participants to list known features for concepts at different hierarchical levels).

CULTURE VERSUS EXPERTISE

There is evidence that as one becomes more expert in an area, what was previously the subordinate level becomes the basic level. For example, *dog* might be a basic-level category for most people, but *poodle* might be a basic-level category for dog trainers (Tanaka & Taylor, 1991; see also Johnson & Mervis, 1997, 1998). This difference in expertise accounts for some of the discrepancies between Berlin's (1992) findings and those of Rosch et al. (1976). One might argue, however, that expertise and culture are not totally dissociable, because as López et al. (1997) argued, knowledge is part of culture (see also Wolff, Medin, & Pankratz, 1999). Furthermore, differences in expertise do not preclude the potentiality for other "cultural" influences to play a role in categorization and reasoning.

An example in which group differences could be attributed to differences in culture, over and above differences in expertise, comes from research by Medin, Ross, Atran, Burnett, and Blok (2002). They examined categorization of freshwater fish among the Menominee and majority-culture European Americans in north-central Wisconsin. Both groups live in an area of Wisconsin with many rivers, lakes, and streams, and both groups have extensive knowledge about the fish that live in those waters. In addition, both groups fish similar species and use similar practices (e.g., fly-fishing, ice fishing). Given these similarities, it is possible to predict that these two groups would share similar conceptualizations of fish.

However, Medin et al. (2002) found differences between Menominee and majority-culture fishermen in categorization of freshwater fish. Importantly, these individuals had high levels of expertise about fish, and expertise did not differ between groups. Nevertheless, these groups exhibited differences in certain tasks. For instance, Medin et al. asked majority-culture and Menominee fish experts to sort name cards of 44 species of local fish into cate-

gories, then examined cross-group similarities and differences. Although a combined analysis showed an overall consensus, Menominee participants exhibited higher within-group than between-group consensus. Majority-culture fish experts showed no greater within- than across-group residual agreement. This analysis suggests that the two groups share a common model but that Menominee experts have an additional basis of organization.

Other analyses reinforce these group differences. Multidimensional scaling of majority-culture sorts yield two-dimensional solutions that correlate with size and desirability. Menominee sorting required an additional dimension corresponding to ecological relations (shared habitat). Majority-culture fishermen were more likely than the Menominee fishermen to give taxonomic or morphological justifications for their sortings (62 vs. 33%, respectively), and the Menominee fishermen were more likely than the majority-culture fishermen to give ecological justifications for their sortings (40 vs. 6%, respectively). These data indicate that levels of expertise (knowledge of a domain) and kinds of experience (practice and goals) cannot fully account for how individuals categorize living things. Later experiments showed that these cultural differences were differences in knowledge organization rather than knowledge per se. For example, a speeded fish-fish interaction task showed large cultural differences (Menominee experts reported more relations, more reciprocal relations, and more relations involving immature fish) that disappeared when the pace of the task was relaxed.

The same difference in cultural orientation was obtained for a group of less expert Menominee and majority-culture fishermen. Based on these findings, Medin et al. (2002) suggested that both experts and nonexperts exhibit a high degree of consensus with respect to fish in their area, but that these groups diverge in a culture-specific way: a difference in the salience of ecological relations as a basis for knowledge organization.

What Do We Know about Categorization as a Basis for Folkbiological Reasoning?

INDUCTIVE REASONING

One primary function of concepts is that they support *reasoning*. One does not need to store every fact and possibility if inferences can be

derived from information that is stored. From the knowledge that all animals breathe, that reptiles are animals, and that rattlesnakes are reptiles, one may reason (deductively) that rattlesnakes must also breathe, even though one may never have directly stored that fact. Indeed, Medin et al. (1997) found that for parks personnel and tree taxonomists who sorted based on morphological properties, the sorting data were a good predictor of performance on reasoning tasks. And as mentioned earlier, López et al. (1997), who investigated taxonomic classification of mammals and similarity, typicality, and diversity effects among Itza' and U.S. college participants, found that although both the Itza' and the U.S. students exhibited similarity and typicality effects when making inductions, only the U.S. students exhibited a diversity effect.

Why are the Itza' not showing taxonomic diversity effects in reasoning? The short answer appears to be that "diversity" is an abstract reasoning strategy that tends to be used by experts only when more concrete causal/ecological reasoning fails. Other work shows that Itza' Maya, U.S. bird experts, most U.S. tree experts, and European American and Native American fish experts do not show diversity effects in reasoning (Bailenson et al., 2002; Burnett et al., 2005; Proffitt et al., 2000). Instead, causal/ecological reasoning dominates. What knowledge seems to provide is flexibility, in the form of a variety of strategies that allow the reasoner to project different properties in different ways. In evidence of this flexibility, Shafto and Coley (2003) found that whereas fishermen projected diseases according to food chain relations among marine animals, they projected more abstract or ambiguous properties like "a property called sarca" among the same animals according to similarity or taxonomic relatedness, as did domain novices.

There is also suggestive evidence of cultural differences among college students in reasoning. For example, Choi, Smith, and Nisbett (1999) found that diversity effects involving specific conclusions (rather than a superordinate category) were weaker among Korean college students than among U.S. college students, at least for biological stimuli. Choi et al. attributed this effect to U.S. students' tendency to think more in terms of categories. They suggested that the fact that both groups show specific diversity effects for social categories reflects the interdependent social orientation of Korean students.

SUMMARY

The results on inductive reasoning echo the findings on categories and concepts: Performance is strongly influenced by domain knowledge, and results with U.S. undergraduates do not generalize very well to other populations.

Is Reasoning from Folkbiological Categories Similarity Based or Theory Based?

Especially within cognitive psychology, folkbiology is an appealing domain from the contending standpoints of both similarity- and theory-based views of categorization and category-based reasoning. On the one hand, our perceptual system is surely an adaptation to the natural world, and if similarity-based models are going to succeed anywhere, it should be here. On the other hand, the biological world is apparently a world of fairly stable clusters of complex features, whose remarkable endurance in the face of constant change presumably owes to naturally occurring causal patterns. Understanding causal patterns in the world is a primary goal of theory-driven knowledge in science, and the history of science is coterminous with trying to understand biological causality in particular. If theory-based knowledge were to develop anywhere outside of science—in other cultures, or in everyday thinking—it should be here.

From the perspective of similarity, there are evident patterns of covariation for biologically related attributes (e.g., toothless, two-legged beings generally have wings, feathers, and can fly). Perhaps most people in the world are aware of these covariations without necessarily understanding their causal origins or interrelations, such as the role of feathers in flight. In other words, there could be quite a bit of biologically relevant data stored but not theoretically assimilated.

Nevertheless, people in different cultures acknowledge, and often try to better understand, at least some of the causal interrelations among covariant biological attributes (Gelman, 2003). These include irreversible patterns of biological growth (maturation) the apparent constancy of covariant morphological, anatomical, and behavioral patterns across generations (reproduction and inheritance); the success of mutually constraining actions of interrelated attributes in maintaining life (bodily function); and the breakdown of interrelated bodily functions (illness and death).

Suppose, as ethnobiologists generally agree, that people everywhere witness certain covariant biological patterns (roughly corresponding to perceptually salient species or genera) but interpret the causal relationships underlying these patterns in different ways. This might suggest that similarity based reasoning precedes theoretically based reasoning, at least in the biological domain. This was a message of developmental studies in the 1980s (Carey, 1985; Inagaki & Sugiyama, 1988; Keil & Batterman, 1984). More recent studies have lowered the age at which children are thought to reason causally about biological kinds. But the origins of causal reasoning in folkbiology remain a matter of controversy.

This controversy hinges on two related questions: (1) What is the earliest age at which children can be said to have a theory of biology? and (2) Does biological thought constitute a distinct domain? Not surprisingly, the answer to these questions depends on how one defines the terms.

THEORY AND DOMAIN

A number of researchers have argued that even very young children's categorization and reasoning is guided by certain skeletal principles (Gelman, 2002) or a framework theory and a unifying concept of an underlying essence that makes things the sorts of things that they are (Gelman, 2003; Gelman & Hirschfeld, 1999; Hirschfeld & Gelman, 1994; Medin & Atran, 2004).

FRAMEWORK THEORIES

Susan Carey (1982, 1985) has shown that children's biological theories guide their conceptual development. In one study, 6-year-old children rated a toy monkey as more similar to people than to a worm, but they also judged the worm to be more likely than the toy monkey to have a spleen (a spleen was described as "a green thing inside people"). Although worms may be less similar to people than are toy monkeys, they are more similar in some respects, namely, common biological functions. And Carey's work shows that children's biological theories help them determine which respects are relevant. Thus, the 6-year-old children's rudimentary biological knowledge influences the structure of their concept of animal (see also Au & Romo, 1999; Coley, 1995; Keil, 1989; Simons & Keil, 1995;

for other studies on the development of biological knowledge, see Hatano and Inagaki, 1999; Inagaki & Hatano, 2002; see Gelman, 2003, for comprehensive reviews).

DOMAIN SPECIFICITY

A number of researchers, especially in the area of cognitive development, have suggested that cognition is organized in terms of distinct domains, each characterized by (usually) innate constraints or skeletal principles of development. For example, naive psychology (theories about people), naive biology (theories about living things), and naive physics (theories about the physical world) may constitute distinct domains with somewhat different principles of conceptual development (see Hirschfeld & Gelman, 1994, for examples).

Although it is difficult to define a domain precisely, the notion of domain specificity has served to organize a great deal of research on conceptual development. For example, there has been a strong focus on the question of whether and when young children distinguish between psychology and biology. Carey (1985) argued that young children understand biological concepts in terms of a naive psychology in which human beings are the prototypical psychological entity. She suggested that only later on do children reorganize their knowledge into a less anthropocentric, biological form in which human beings are simply one animal among many. It is possible, however, that these results were driven by the relatively impoverished experience that children from large cities may have with nature. Rural European American and rural Native American children do not show this anthropocentric pattern (Ross, Medin, Coley, & Atran, 2003). In any event Carey's (1985) claims have sparked a great deal of research, and the current consensus is that young children do have biologically specific theories, though they may differ in content and degree of elaboration from those of adults (for extensive reviews, see Gelman, 2003; Inagaki & Hatano, 2002; Keil, 1989). Some of this research involves children's understanding of *essences*, a topic to which we next turn.

PSYCHOLOGICAL ESSENTIALISM

One way of integrating similarity and explanation is through psychological essentialism (Gelman, Coley, & Gottfried, 1994; Keil,

1989; Medin & Ortony, 1989). The main ideas are as follows: People act as if things (e.g., objects) have essences or underlying natures that make them the thing that they are. Essentialism is an idea present in many cultures (e.g., Atran, 1990; Walker, 1992). For biological categories in our culture, people often identify essence with genetic structure. The essence constrains or generates properties of organisms that may vary in their centrality. For example, people in our culture believe that the categories *male* and *female* are genetically determined, but to pick out someone as male or female we rely on characteristics such as hair length, height, facial hair, and clothing that represent a mixture of secondary sexual characteristics and cultural conventions. Although these characteristics are less reliable than genetic evidence, they are far from arbitrary. Not only do they have some validity in a statistical sense but also they are tied to our biological and cultural conceptions of male and female.

Why should people act as if things have essences? Possibly the reason is that it may be a good strategy for learning about the world; that is, our perceptual and conceptual systems appear to have evolved such that the essentialist heuristic is very often correct (Atran, 1990; Medin & Wattenmaker, 1987; Shepard, 1987). Classifying on the basis of similarity will be relatively effective much of the time, but that similarity will yield to knowledge of deeper principles. Gelman and Wellman (1991) showed that even young children seem to use notions of essence in reasoning about biological kinds (see also Gelman & Hirschfeld, 1999). Susan Gelman has systematically traced the development of essentialism and its role in conceptual and linguistic development (see Gelman, 2003, for a review).

The third experiment by Gelman and Wellman (1991) provides an example of a method for examining children's beliefs about nature versus nurture in biology. Children were told a story about a baby who, shortly after birth, was taken away from the birth parent to live with animals of a different species (a between-species manipulation). Importantly, the children were told that the baby never saw another animal of its mother's species again. Once children heard the story, they were asked whether the baby would have a particular property possessed by the birth parent or a particular property possessed by the adoptive parent when it was all grown up. Some of the

properties were behavioral (e.g., a horse's neigh and a tiger's roar) and some of the properties were physical (e.g., kangaroos have a pouch and goats do not have a pouch). All of the properties were "known" in that they were category-typical properties about which the children would already have had some knowledge. Results showed that 4- and 5-year-old children exhibited a birth bias (i.e., they were more likely to say that the baby had the same property as the birth parent rather than the adoptive parent) for both behavioral and physical properties.

This initial study has sparked a number of other investigations, some driven by methodological issues and others aimed at testing the cross-cultural universality of a birth bias in children's reasoning. The upshot is quite strong support for a widespread birth bias in young children, even though adults' patterns of reasoning diverge across studies (e.g., Astuti, Solomon, Carey, Ingold, & Miller, 2004; Atran et al., 2001; Sousa, Atran, & Medin, 2002; Waxman, Medin, & Ross, in press).

We have presented only one theory and one interpretation of the data from the adoption properties paradigm. It would be misleading to imply that there is any strong consensus on essentialism. For example, as some researchers argue the key is that people are sensitive to causal relations, and that the notion of an essence is not needed (e.g., Rehder & Hastie, 2001; Rips, 2001; Strevens, 2000; see Ahn et al., 2001, for counterarguments).

Summary

Although it is hard to summarize across vast literatures, our impression is that the more categories are grounded by real-world contingencies, the greater the cross-cultural agreement in categorization. For example, in the domain of biology, the most relevant and informative rank corresponds to the scientific level of genus (and in most local contexts to species), and cross-cultural agreement is also the most unequivocal at this level (e.g., Berlin, 1992; Malt, 1995).

Cross-cultural studies of people's biology have influenced cognitive theories of concept and categories in at least two distinct ways. One is that undergraduates at major U.S. universities are often the "odd group out," and "standard" results do not hold up well to cross-cultural scrutiny (see Medin & Atran,

2004, for a summary). The other is that extensive experience with the same biological kinds (involving the same activities and goals) does not guarantee convergence with respect to conceptions of living kinds. In particular it appears that cultural groups differ substantially in their understandings of relations among kinds or, in other words, in their folkecology.

Another way to state this generalization is to note that shared categories need not imply shared meanings. For example, Atran et al. (2002) studied Itza' Maya and Ladino agroculturalists in Guatemala and noted that the Ladino term for the forest (*tierra agarrada de nadie*) translates into "the land guarded by no one," contrasting sharply with the Itza' Maya tendency to refer to the forest as *ki-wotoch*, which translates as "our home." Guess which group has more sustainable practices? The point is that a major source of cultural differences is not in fixing reference but rather in meanings, which may guide attitudes and behaviors. We now turn to a second critically important domain, social reasoning.

SOCIAL CATEGORIES AND CULTURE

The ability to categorize individuals into social categories is fundamental to interpreting and predicting the behavior of others. Indeed, given the complexity of human cultural life, the competencies underlying social categorization are among the most important human reasoning capacities. Therefore, it is not surprising that these competencies are grounded in our species' evolutionary past and are among the earliest discriminations human infants make. Many species, including most nonhuman primates, inhabit complex social environments in which the capacity to identify and classify conspecifics is paramount. Chimpanzee social relationships, for example, require the capacity to distinguish other chimps with respect to sex, age grade, kin relation, residential group, as well as position in status hierarchies (de Waal, 1998). Given how deeply rooted these distinctions are in human natural history, we should not be surprised to find that human *infants* display precocious sensitivity to the age (Brooks & Lewis, 1976), gender (Miller, 1983), language spoken (Mehler et al., 1988), and even race (Kelly, Quinn, & Slater, 2005) of other humans in their environment.

Intriguingly, despite the evident universal dimensions of the capacity for social discrimination and ultimately categorization, the degree to which social categories are contingent aspects of culture is striking. Anthropologists, comparative sociologists, and historians have documented extraordinary differences in the way peoples partition and reason about the social world. Even those classifications that otherwise seem grounded in natural "fact" vary dramatically across cultures. Consider the classification of kinfolk. On the one hand, as anyone who has witnessed a young child acquire language knows, kinterms such as *Mama* and *Papa* are invariably among the first words produced and understood (Hirschfeld, 1989). On the other hand, and perhaps less familiar to many readers, the classification of kin, at least to the anthropologist, is the preternaturally varying system of cultural categorization. Particularly for speakers of English, kinship categories represent the cultural recognition of relations of procreation and affiliation, and more or less accurately map them linguistically (Goodenough, 1955). All "full" siblings are biologically equally close relations, first cousins are somewhat less so, second cousins, even less so, and so on. Yet the thrust of kinship studies—which *was* largely what anthropologists studied during much of the 20th century—has been the demonstration that understanding consanguinity requires an understanding of the specificities of cultural tradition, not the universals of human procreation (Schneider, 1980).

As an illustration, consider the system of kin classification of the Batak of highland Sumatra, with whom one of us (LH) worked. Kin categories not only identify relations of consanguinity but also specify what these relations *mean*. In the case of the Batak system, kin categories pick out proscriptive marriage partners (in fact, this system, found throughout much of southeast Asia, has figured in one of anthropology's most influential debates [Leach, 1970; Lévi-Strauss, 1949]). In contrast to the American system, in which marriage between first cousins is generally avoided, among the Batak, kin classified as parallel cousins (the child of a parent's same-sex sibling; e.g., the father's brother's child) are in the same category as one's siblings. Accordingly, marriage between them is prohibited. On the other hand, cross-cousins (the child of a parent's opposite-sex sibling; e.g., the mother's brother's daughter) are

preferred marriage partners. Blatantly, these contrasting classifications do not reflect relations of biological proximity; parallel and cross cousins are equally close biologically.

The classification of kinfolk, of course, is not the only system of “natural” categories that vary across cultures. Even “givens” such as “sex” (*not* gender) vary intriguingly across cultural traditions, as Laqueur (1990) demonstrated in his history of the shift from a one-sex system to the modern two-sex system. The notion of *child*, on the one hand, is evidently a universal (e.g., infants are able to discriminate between children and adults, *and* to distinguish both from midgets), but it is also widely recognized as a cultural construction (Ariès famously [1962] argued that children were not recognized as a distinct category of being prior to the 15th century). As with most categories, a particular pattern of partitioning a domain is linked to a particular pattern of reasoning about the domain as well. In contemporary U.S. society, for example, children are typically not considered capable to cross a busy street without supervision, whereas 8-year-olds are preferred caregivers for infants in much of the world (Morelli, Rogoff, & Angelillo, 2003).

As with many systems of categorization, the study of social categories therefore involves a tension between attention to their universal psychological bases and to the considerable cultural variation that mark them. Our goal in this section is to address this tension directly, and in doing so, we take an approach that is distinct from many other chapters in this volume. Among other things, we do not pretend to present a balanced or comprehensive review of existing work on culture and social categorization. Rather we suggest, following Sperber (1996), that much cultural variation in cognition is best explained by identifying the factors that shape the distribution of cognitive representations within a given population. This approach does not assume, or even favor, identifying either the boundaries or key features (symbols, meanings, propositions, regimes of truth, etc.) of a particular culture. Sperber’s epidemiological theory does not oblige us to distinguish between cultural and other forms of knowledge but simply requires that we identify the factors underlying the (more or less) stable, recurring distribution of representation in a particular population. Nor, in this view, is it assumed that all linked cultural phenomena can be mapped on the same population (i.e., have

identical distributions) or that the same factors underlie the distribution of different cultural phenomena within the same cultural tradition. In brief, culture is more or less a sort of thing, not a unique level of variation.

Sperber’s (1996) approach does not discount cultural variation. Rather, it holds that cultural variation can in significant measure be explained as the outcome of the operation of invariant cognitive processes. Specifically, Sperber argues that variation in the distribution of many cultural phenomena is governed by evolved and modular, domain-specific cognitive competencies that render some representations “catchier”—hence, more widely and stably distributed—than others. It is not that these cognitive competencies are dedicated to producing cultural phenomena—that they were evolved to output cultural phenomena. Rather, culturally varying representations are produced by these competencies and are exploited for cultural purposes. Sperber gives as an example the widely varying and culturally important elaborations of human faces found in virtually all cultures. Ranging from special-purpose makeup to sculpture to masks to gargoyles, the ubiquity *and* variation in the cultural elaboration of faces rest on an evolved and robust capacity to identify and remember human faces, even from degraded and/or programmatic representations (e.g., a circle with two dots and a dash). Plausibly evolved to track individual persons and their actions, the special *psychological* salience of human faces makes them excellent objects of cultural variation, if *excellent* in this context means “widely and stably distributed.”

We propose that parallel, domain-specific processes underlie cultural variation in some social categories. Humans, we suggest, are endowed with a psychological module—elsewhere Hirschfeld (1996) has referred to it as “naive sociology”—that governs the development of the capacity to reason about others’ actions by virtue of their membership in social groups. Although the competency for naive sociology may be innately prepared, elaborations of its output vary substantially across cultures. Indeed, our proposal is that social categories are central to virtually all systems that regulate and organize human behavior *precisely because* these systems are so easy to learn and remember, and they are so easy to learn and remember because they are grounded in a universal, cognitive competency.

To understand better the nature and scope of the modular competence for naive sociology, it is useful to identify and contrast it with another evolved, domain-specific capacity for understanding the behavior of others. In addition to reasoning about people with respect to memberships in groups, humans readily account for the actions of others as a function of other unseen mental states and dispositions. In previous research, the two capacities have typically been studied independently, giving the impression that they may represent distinct phenomena. But as Hamilton and his colleagues argue, group-based reasoning in fact relies on the same cognitive mechanisms and processes as person perception (Crawford, Sherman, & Hamilton, 2002; Hamilton & Sherman, 1996). To the contrary, we argue that each of these capacities is based in a distinct evolved, modular device. Theory of mind (ToM)—the capacity to interpret and predict another's actions on the basis of unseen mental states—appears to be a species-specific capacity (Povinelli & Bering, 2002; Tomasello, Call, & Hare, 2003). Frith and Frith (2003; Gallagher & Frith, 2003) provide evidence that ToM involves a special-purpose neurocognitive module. Although culture is likely to elaborate, highlight, or place them in the background, clearly these attributions of intentional states have an innate basis.

Reasoning about individual persons involves both attributions of transient mental states (Johnny stole a cookie from the cookie jar because he *believed* that cookies were in the cookie jar, and he *believed* that consuming them would satisfy his *desire* to sate his hunger) or enduring dispositions and traits (Johnny stole a cookie from the cookie jar because he is an intrinsically *dishonest* person). Conventional psychological wisdom about both transient mental states, particularly emotions, and dispositions and traits has been challenged during the last two decades (as several chapters in this volume attest) by anthropologists (Lutz, 1988) and cultural psychologists (Markus & Kiyama, 1991). It is important to distinguish, at least in this context, between how peoples *talk* about motivation to act and how such motivation is actually psychologically achieved. Johnny may say that he believes in ghosts, when in fact he does not believe that sentient creatures can pass through solid objects (Atran, 2002; Barrett & Keil, 1996; Boyer, 2001), and at the group level, Johnny might say that the Nuer believe in ghosts. But the Nuer do not ac-

tually believe anything, only individual Nuer form beliefs—in particular, Johnny-the-Nuer's beliefs about what the Nuer supposedly believe (Sperber, 1996).

Even though cultures vary widely in the degree to which attributions of mental states and attributions of dispositions and traits are engaged, the cognitive processes that make such attributions possible vary little across cultures. Experience also does not significantly alter the individual's capacity to make either kind of attribution. For example, living in a cultural environment that disprefers attributions of dispositions and traits in favor of more interdependent representations of self does not reduce the individual's *capacity* for such attributions (Nisbett, 2003). Similarly, being reared in a more communal cultural environment does not reduce the individual's capacity, if not proclivity, to interpret behavior in terms of private, individually experienced mental states (Avis & Harris, 1991).

Our concern here is the human capacity to use group membership in interpreting and predicting the actions of others (Berreby, 2005; Furth, 1996; Hirschfeld, 1989; Jackendoff, 1992). Membership in social groups serves to identify both the *kind* of person an individual is and the *roles* the individual may assume. It also *explains* behavior as a function of group affiliation. The hypothesis that this sort of explanation is the result of the operation of a modular cognitive competency is supported by several lines of research. The first concerns the range of variation in *types* of social categories encountered. Despite considerable variation in their elaborations, surprisingly few dimensions of social difference predominate in all cultures and across all historical epochs: sex/gender, age, kinship, language spoken, and race/ethnicity. Each of these social dimensions, across a broad range of cultures, is seen as having a particular essence that governs the development and behavior of the organism (Gelman, 2003; Haslam, Rothchild, & Ernst, 2000; Hirschfeld, 1996; Mahalingham, 1998). As we observed earlier, the ability to classify people over these types of categories emerges quite early, in some important respects during infancy (for gender, see Miller, 1983; for age, see Brooks & Lewis, 1976; for language spoken, see Mehler et al., 1988). This kind of robust development, in which cultural experience appears to have limited effect, is a hallmark of a modular competence.

A second line of supporting evidence comes from considerable research on stereotyping. A number of studies have now demonstrated that many stereotypes are based in nonconscious, automatic processes (e.g., similarity judgments, categorization formation, within- and between-category biases [Greenwald & Banaji, 1995; Hilton & von Hippel, 1996], among other strategies of category-based reasoning under uncertainty). Relevant to this discussion is work demonstrating that even quite young children are subject to subtle social biases. Children, like adults, show ingroup favoritism even when membership is based on trivial commonalities (Nesdale & Flesser, 2001). Recent studies have demonstrated the early emergence of a susceptibility to stereotype threat (Ambady, Shih, & Kim, 2001), strikingly at an age when racial and ethnic stereotypes play virtually no role in shaping children's behavior. Imaging studies suggest that the perception of and reasoning about race and racial stereotypes may involve unique patterns of neural activation (Eberhardt, 2005; Hart et al., 2000; Phelps et al., 2000; Richeson et al., 2003; Wheeler & Fiske, 2005).

These findings aside, most work on stereotypes in social psychology would not be thought to support the domain-specific competency hypothesis we propose. Indeed, according to a long-standing view in social psychology, social categorization differs from other object categories only to the degree that social categories are object categories whose target stimuli are people (Hamilton & Trolier, 1986). A developmental corollary is the widely held claim that stereotypes arise through a process of social learning: Children are exposed to stereotypes, particularly those expressed by important adult models such as parents and teachers, and as a result, come to hold them (e.g., Powlishta, Sen, Serbin, Poulin-Dubois, & Eichstedt, 2001).

Social learning presupposes social modeling, particularly modeling of attitudes and practices by parents, teachers, and other significant persons in the child's environment. "As the twig is bent, so grows the tree" goes the old saw. Yet several studies show that children's racial and ethnic biases are not reliably associated with the beliefs and attitudes of parents or peers. This is the case even when children believe that their attitudes correspond to those of parents and peers, and even when parents intervene to shape directly their children's racial and ethnic

attitudes (Aboud & Doyle, 1996). These findings are inconsistent with the view of social development, according to which young children's early understanding of social categories is tethered to surface differences in appearance. Young children, according to this view, grasp neither racial nor gender constancy, instead believing that superficial and reversible changes in skin color actually change an individual's racial identity or that superficial aspects of appearance such as hair length or gendered clothing determine one's gender. Finally, according to this model, it is only as children mature that their understanding becomes more adult-like (e.g., grasping the notions of racial and gender constant, and eventually coming to understand both as functions of a person's biological constitution/heritage). For example, Aboud and Skerry (1983) found that when Canadian 5-year-olds were shown pictures of a familiar Anglo child dressed in traditional Eskimo clothing, most agreed that the child had become Eskimo. Semaj (1980) found a similar pattern of reasoning when he asked young children whether a child's race would change if he wore a blond wig and light makeup; they also judged that the child's race would change.

Our proposal predicts a different pattern of development: Even early representations of social groups are theory-like and untethered to perceptual appearance. Thus, like the modular competencies for folkbiology, ToM, naive physics, and numerosity, a competence for naive sociology predicts that children develop largely on their own more adult-like knowledge of social groups, and form more adult-like representations of them. Hirschfeld (1996) speculated that children may have found Aboud and Skerry's (1983) and Semaj's (1980) transformation tasks difficult, because the changes were both implausibly abrupt and difficult to integrate with gradual changes typical of biological processes. To rule out this possibility, Hirschfeld (1996) asked preschoolers whether racial and other corporeal properties could change in the familiar context of transformations that occur over one's lifespan and over generations. When asked which property would remain unchanged as a person grew up (hair and skin color vs. clothing style and color), even 3-year-olds judged that racial properties were more constant than sartorial ones. More strikingly, when asked which property would remain unchanged as a person grew up (hair and skin color vs. body build), 4-year-

olds judged that racial properties were more constant than body build. The same pattern of judgment was obtained when Hirschfeld asked which properties would remain constant between a parent and his or her child (i.e., if a heavyset parent was black he was more likely to have a thin, black child than a heavyset white one).

Similar results were found when Hirschfeld (1996) asked preschoolers whether a child would develop racial properties matching her birth parents or those of her adopted parents. Hirschfeld's studied the judgments of North American and Northern European children; however, the same theory-like understanding of race has been documented by Giménez and Harris (2002) among Spanish preschoolers, by Astuti et al. (2004) in their work with 6-year-olds in Madagascar, and by Mahalingham (1998) in his study of South Asian preadolescents.

Modular competencies also appear to channel children's attention to specific kinds of things (e.g., with folkbiology, nonhuman living organisms, or with naive physics, the relationship between the movements of objects). In domains, such as naive sociology, in which cultural input evidently plays a significant role, the modular competence specifies that membership in essentialized groups is particularly informative, it does not specify whether the essentialized group is a race, as in contemporary North America, or caste, as in contemporary South Asia; the relevant entities are inferred from cultural information rather than given by the environment. A crucial task for the child is to determine which sources of cultural knowledge are likely to provide the most relevant information. In conventional social learning theory, it is assumed that parents and teachers are the best sources of information. As observed earlier, however, this does not appear to be the case with racial information. On reflection, this is hardly surprising: If children are to develop culturally meaningful understanding, they should look to culturally meaningful sources of information. Relying on very local sources—say, a particular family tradition or a particular teacher's image of the world—risks forming beliefs that may be marginal to the dominant cultural traditions. If, however, the child attends to representations in the larger community, then her knowledge is more likely in line with the broader contours of the cultural tradition in which she participates. The issue

is essentially one of sampling. In the case of the young child, it means attending to—privileging—less frequently encountered sources over more frequently encountered, local ones.

As an illustration, consider the development of accent. Young children of non-native speakers do not develop the accents of their parents. They develop normative speech patterns, often not well modeled by their parent (Harris, 1998; Hirschfeld, 1996). Presumably this occurs because the local source of linguistic information is discounted relative to less local, and less frequently encountered, sources. Somehow the child knows to sample the broader speech community in language learning. If our proposal is correct, then we would expect to find examples of this sampling bias in the development of social categories, particularly in reasoning based on social category membership. In support of this claim, Hirschfeld (1996) conducted a study examining the development of the “one drop of blood rule,” the culturally specific expectation that a person with any traceable black ancestor is black. Children's interpretation of racial admixture was not found to be shaped by race, as social learning theory would predict. By age 12, children living in a predominantly white city judged that a child with one black parent would have phenotypically black features. Black 12-year-olds living in a community with a large minority population, in contrast, judged that a child with one black and one white parent would look mixed. The crucial case was the white children living in the community with a large minority population. Like black 12-year-olds from the same community, the white children judged that the mixed-race couple would have a child that looked mixed. In short, children's reasoning about race was more influenced by community—the cultural environment—in which they lived than by their race/ethnicity.

In summary, social reasoning makes use of a variety of skills and competencies, but there is emerging evidence that key competencies are invariant across cultures and are likely to be in part innate. In the domain of reasoning about individual persons, attributions of mental states and traits are likely to be grounded in one innate module, whereas in the domain of reasoning about individual persons as members of groups, there seems to be an innate preparedness to detect group memberships and use them as the basis for social inference. Cultures are likely to exploit such innate compe-

tencies, advantaging cultural representations whose stability and recurrence are enhanced by them. Cultural variation and universal psychological processes are not opposing explanations but are instead functions of the same human cognitive architecture.

OTHER ISSUES TO CONSIDER

The following section addresses additional methodological issues that should be considered when conducting research on culture, categorization, and reasoning. Included in the discussion of these issues is a brief introduction to other kinds of concepts (e.g., non-natural kinds, emotions) not covered earlier in this chapter. Reference to these kinds of concepts is included in this chapter for completeness, but readers interested in a more comprehensive review should refer to the literature cited in this section and beyond.

Task Sensitivity

When searching for cultural differences, it is important to consider whether the task being used is sensitive enough or appropriate for finding cultural differences. For instance, replicating earlier work by Chiu (1972) and Nisbett and colleagues (2001), Unsworth, Sears, and Pexman (2005) found that Chinese adults are more likely to group both natural and non-natural kinds together if they share a relationship (e.g., a car and a tire), and that Canadian adults might be more likely to group natural and non-natural kinds together if they belong to the same category (e.g., a car and a bus). However, cultural differences in categorization were not observed in a timed categorization task, although differences in response latencies were analogous with the differences in categorization found in the previous experiment. The authors interpreted the results as suggesting that differences in categorization styles are associated with differences in semantic activation, but, importantly, they noted that the results also suggest that the nature of the categorization task may determine the extent to which these cultural differences are observed. Interestingly, Medin et al. (2002) found the opposite pattern to that found by Unsworth et al. (2005), such that cultural differences were observed in a speeded task but disappeared in an un-speeded task (this study is described in more detail in an

earlier section of this chapter). Medin et al. (2002) suggested that the cultural differences observed were due to differences in “habits of the mind” that are more easily observed in a speeded task. If such an explanation is correct, then it is unclear why the opposite pattern was found by Unsworth et al. (2005). This inconsistency would be interesting to follow up in future research. Importantly, though, both studies reveal the importance of considering whether the task is sensitive enough to detect cultural differences. Such considerations could impact the kinds of conclusions drawn about the variability of particular aspects of cognition across cultural communities.

Elaboration of Concepts

Yet another issue to bear in mind is whether an investigation of cultural differences is “deep enough,” that is, whether the myriad ways in which concepts can differ across communities have been explored. Two areas of research that could benefit from further analysis include the studies of emotion concepts and of artifact concepts.

A number of researchers have investigated the extent to which emotion concepts vary across cultural communities (e.g., Boster, 2005; Ekman, 1972; Izard & Buechler, 1980; Johnstone & Scherer, 2000; Kim & Hupka, 2002; Lutz, 1988; Markus & Kitayama, 1991; Páez & Vergara, 1995; Romney, Moore, & Rusch, 1997; Rosaldo, 1984; Russell, 1991; Scherer & Wallbott, 1994; P. B. Smith & Bond, 1993; Wierzbicka, 1992).

Research about emotion concepts and culture has primarily focused on the extent to which emotions are biologically determined, and therefore universal (e.g., Ekman, 1972; Izard & Buechler, 1980), or socially constructed, and therefore culturally relative (e.g., Lutz, 1985, 1987, 1988; Rosaldo, 1980, 1984). Although some researchers argue in favor of one or the other of these two extremes, most researchers adopt a kind of hybrid theory, in which they believe that some components of emotions, such as certain physiological responses (e.g., facial expressions, the release of particular hormones) may be experienced universally, but that the way particular emotions are displayed and the kinds of emotion categories people form may be culturally specific.

The kinds of similarities and differences researchers might examine include (1) whether

an emotion is lexicalized or not; (2) the degree of correspondence of lexicalized emotion terms across cultures; and (3) whether there are differences in rules about expressions of emotions and conceptualizations about whether the resulting behaviors are voluntary or not (e.g., running amok).

It is well-known that there is substantial cultural variability in lexicons of emotion. Thus, many cultures have at least several emotion words that correspond to basic emotions such as joy, anger, sadness, fear, and disgust, but some cultures have only a few words for these emotions (Russell, 1991). Nevertheless, when words for basic emotions are present, there is an impressive cross-cultural similarity in the meanings of these words. For example, Scherer and Wallbott (1994) asked participants in 37 countries across five continents to complete questionnaires about seven different emotions (joy, anger, fear, sadness, disgust, shame, and guilt). Participants first recalled experiences in which they felt each emotion and were then asked specific questions about those emotional experiences. Results revealed that the seven emotions differed substantially from each other, and that geographical and sociocultural differences were observed, but such differences were much smaller than the overall differences between the emotions themselves. A similar conclusion was obtained by Kim and Hupka (2002), who compared Koreans and Americans, and Romney et al. (1997), who tested perceived similarities of English and Japanese emotion terms.

However, Boster (2005) has pointed out that such research often involves an attempt to match semantic meanings of emotion terms using methods such as back-translation, and that such methodology can be problematic in assessing cross-cultural variation. In particular, translation methods often occur before data collection, so it is not surprising to see cross-cultural agreement elicited by terms that have been chosen specifically because they correspond to each other across languages. Furthermore, although other research may not rely on translation as a first step (see Russell, 1983, 1989), such research often involves similarity judgments on only a couple of shallow dimensions (e.g., evaluation [positive, negative], arousal) that may not capture deep semantic structure and might therefore fail to capture important semantic variations across cultures. To examine emotion concepts at a deeper level

of analysis, future research might include an investigation into whether some cultural groups elaborate a subset of emotional concepts (e.g., those associated with guilt in Japan) more than others, or whether expressions of particular emotions vary with respect to social roles in some cultural groups more than in others. One useful approach for future research might be to conduct ethnographic studies to generate further predictions about where cultural differences might exist and to obtain a more comprehensive understanding about the nature of particular cultural differences.

Studies examining culture and the concepts of artifacts have led to conclusions similar to those made for cultural differences in emotion concepts, namely, that differences in naming practices can sometimes be much more pronounced than conceptual differences. For instance, Malt, Sloman, Gennari, Shi, and Wang (1999) asked English-, Chinese-, and Spanish-speaking adults to categorize nonnatural kinds (60 different bottles and jars) explicitly on the basis of different kinds of similarity, and after several types of analyses, concluded that there were no cultural differences in these similarity-based sorts. Importantly, Malt et al. noted that there is little agreement about the most relevant features for artifact categorization, so separate sorts were based on similarity of physical qualities (e.g., what it looks like, what it is made of), similarity of function (e.g., how it is used), and "overall" similarity. None of these sorts produced cultural differences. However, Malt et al. did find substantial differences in naming patterns for these objects (whether the item is named a bottle, a jar, or a container, etc.), suggesting that the relationship between similarity and naming of these artifacts is not very straightforward. Further research should examine whether cultural differences in categorizing the objects emerge if categorization is based on other dimensions (contextual relevance of particular bottles, etc.; conceptual elaboration of particular bottles) and whether these different types of sorts map more directly onto naming patterns in the different communities. Again, ethnography would be a useful tool in this regard.

Attribution of Differences

Once cultural differences have been found, it is important to consider whether the differences can really be attributed to differences in the

concept or process of interest, or whether there is an alternative explanation for the results. For example, Norenzayan, Smith, Jun Kim, and Nisbett (2002) argued that East Asians were less likely than European Americans to abandon intuitive reasoning (i.e., reasoning based on experience and information from the senses) in favor of formal reasoning (i.e., reasoning based on rules and formal logic), and although some of their findings are compelling, other results must be considered with caution. In Experiments 1 and 2 they found cross-cultural differences in categorization and conceptual structure, and in Experiments 3 and 4, cross-cultural differences in deductive reasoning. However, the cultural differences observed in Experiment 4 are not attributable to differences in deductive reasoning or even to intuitive or formal reasoning more generally. We shall soon see why.

In the fourth experiment, Norenzayan et al. (2002) examined cultural differences in deductive reasoning by giving Korean and U.S. college students valid and invalid arguments that were either abstract or concrete; for the concrete problems, the conclusions were either believable (consistent with real-world knowledge) or unbelievable (inconsistent with real-world knowledge). The groups did not differ on the abstract problems, but Norenzayan et al. found that Koreans were less likely than were U.S. college students to endorse concrete arguments with unbelievable conclusions. They concluded that the Koreans' reliance on intuitive reasoning led to less accurate responses in this task.

The Norenzayan et al. (2002) results are not unambiguous, in that they do not separate response biases (i.e., the tendency to be more or less liberal when deciding to accept an argument as valid) from the ability to distinguish between valid and invalid arguments. In fact, Unsworth and Medin (2005) showed that Korean participants overall were much less likely to accept an argument as valid, and that cultural differences in reasoning disappeared when response biases were taken into consideration. The reason for the cultural difference in response bias or criterion setting is unclear, and this particular finding would be interesting to examine more closely in its own right. Furthermore, future research specific to deductive reasoning might profit by narrowing the examination to a domain in which specific cultural differences might be expected (e.g., Meno-

minee deductive reasoning in the domain of biology, or Chinese deductive reasoning in the domain of social relationships).

SUMMARY AND CONCLUSIONS

We are very much in the position of describing a moving target. The intersection of culture, categorization, and reasoning currently is receiving a great deal of attention, and new empirical findings appear almost daily. This field of research has largely overcome its ugly beginnings, in which cognitive tasks developed in Western countries were transported wholesale to other cultures, and contexts and any differences noted were interpreted as deficits (see Cole & Scribner, 1974, for a review). We say "largely" because cultural research needs to be constantly vigilant about "home court assumptions" that get in the way of our understanding other cultures. We see room for both broad contrasts based on a few dimensions of difference and very specific examinations of single cultural groups. But to yield powerful generalizations, the broad contrasts will have to be coupled with careful ethnography and sociohistorical analyses. We have tried to show that a serious concern with the fine-grained, typically narrative specificity of ethnographic and historical investigations does not mean abandoning psychology's powerful theories and methods, honed in laboratory studies. Social scientists have long been skeptical of the "anthropological veto," the claim that since it does not happen like that in Pago Pago, one has got it wrong (see Bloch, Solomon, & Carey, 2001, for a nice example of the tension between experimental probes and ethnographic observation). It is uncontroversial that cognition, no matter how widely a *task* may be distributed, is something that happens in individual minds. It is no more controversial that individual minds inhabit complex cultural environments—indeed, that the mind's evolution was profoundly shaped by complex cultural circumstances. Categorization and reasoning simply cannot be understood without taking into account both the mind and the environment that supports it.

In the same vein, we believe that it is impossible for studies of single cultures to be theoretically neutral. Therefore, the promise for this field lies on middle ground, where both within- and between-culture similarities and differ-

ences are recruited in the service of understanding how culture affects thought. As we have seen, triangulation can be an effective strategy for understanding both within-culture differences and across-cultural similarities. In addition, the CCM has proven to be a useful tool in the service of understanding variation. In ongoing work in Guatemala and among cultural groups in Wisconsin, we are collecting social network data along with cognitive measures to see whether similarities in values and beliefs can be linked to social network proximities. If so, we may be in a position to observe cultural processes at work.

Finally, it is also worth pointing out that attending to complex cultural environments does not require *cross-cultural* research. In other words, research that is sensitive to cultural processes does not necessarily require observations of *differences* or comparisons *between* cultural communities to be meaningful and interesting. Simply directing attention towards any community not typically represented in psychological research will help to inform our understanding of cognitive and psychosocial phenomena in new and exciting ways. Given the overwhelming focus of cognitive research on U.S. college students, it behooves us to do meaningful ethnography, apply consensus analysis, and employ converging measures, with the goal of understanding the nature and dynamics of their culture.

NOTE

1. The notion of “cultural epidemiology” has two distinct traditions: one focused on the relatively high-fidelity “reproduction” and patterning of cultural (including psychological) traits within and across human populations, and the other focused on the ways cognitive structures “generate” and chain together ideas, artifacts, and behaviors within and across human populations. Jacques Monod (1971), the Nobel Prize-winning biologist, was the first to use the concept of “culture as contagion”—although more as metaphor than theory. Cavalli-Sforza and Feldman (1981) were pioneers in working out a theory in which culture is conceptualized as distributed through a population; however, no microscale cognitive processes or structures were modeled or considered, only macroscale social psychological traits. Lumsden and Wilson (1981) explicitly advocated a theory of culture as distributed mental representations, but the combination of a high degree of mathematical sophistication and a rudimentary awareness of basic conceptual structures failed to spawn any further serious research along their lines.

Two more fully developed epidemiological approaches soon emerged. Boyd and Richerson (1985) were able to show how biases in transmission, such as prestige or conformism, could help to explain the spread and stabilization of macrosocial psychological traits among populations. Sperber (1985) provided the first theoretical blueprint for how individual-level microcognitive structures (as opposed to invocation of imitation or other cultural reproduction processes) could account for cultural transmission and stabilization. Until now, there has been little fruitful interaction between these two traditions (see Laland & Brown, 2002; Henrich & Boyd, 2002). We believe that these two “epidemiological” traditions are compatible, and our empirical example suggests that they can be mutually informative.

CHAPTER 26

Culture and Memory

QI WANG
MICHAEL ROSS

Every introductory psychology text has a chapter on memory. Students learn that Hermann Ebbinghaus, a philosopher, began the scientific study of memory in the late 19th century by testing his own recall for thousands of letter strings. They learn that the memory system has different components, including shorter and longer term memory storages. They learn about different forms of memory, such as semantic, episodic, source, declarative, and implicit memory, and that these different kinds of memory appear to be encoded in different parts of the brain. Students learn that even information that is encoded in the brain can be forgotten and misremembered for various reasons, that some, but not all, types of memory decline with normal aging. They learn that brain injuries, traumas, and diseases can have highly selective effects on memory, destroying particular forms of memory while leaving other types intact. Students learn all of this and much more—including that some of the claims in this paragraph are controversial. Students typically do not learn, however, that social psychological and cultural factors influence memory.

Just as memory researchers disregard social psychology, social psychologists tend to neglect memory. In describing topics that social psy-

chologists study, the website for the Society for Personality and Social Psychology states: “By exploring forces within the person (such as traits, attitudes, and goals) as well as forces within the situation (such as social norms and incentives), personality and social psychologists seek to unravel the mysteries of individual and social life in areas as wide-ranging as prejudice, romantic attraction, persuasion, friendship, helping, aggression, conformity, and group interaction.” One searches in vain for any mention of memory.

Such reciprocal neglect is understandable. Memory seems to encompass basic cognitive and neurological processes that transcend social context and culture. To be consciously remembered, information has to be noticed and encoded in memory, and that is presumably true whether a person lives in Beijing, Bombay, or Boston. Nevertheless, Frederic Bartlett (1932), a pioneer in the study of memory, entitled his classic book, *Remembering: A Study in Experimental and Social Psychology*. Unlike many of his peers who studied university students’ recollections of Ebbinghaus’s letter strings, Bartlett investigated recall of meaningful material in different social contexts. First, he discovered that people’s perceptions, understanding, and memory of new information are

strongly influenced by their prior knowledge, or in Bartlett's own term, schemas. Second, Bartlett insisted that memory is often an active construction rather than the simple recovery of information stored in the brain: "What is said to be reproduced is, far more generally than is commonly admitted, really a construction, serving to justify whatever impression may have been left by the original. It is this 'impression,' rarely defined with much exactitude, which most readily persists" (p. 176). Thirty-five years later, Neisser (1967) made a similar point, arguing that only fragments of an episode are stored in memory. He suggested that people reconstruct an event from these bits of memory, just as a paleontologist reconstructs a dinosaur from a few bones. Building upon this framework, we examine in this chapter the impact of culture on schemas, and how prior information in the form of shared knowledge shapes the constructive process of memory.

If cultural and social factors are often neglected in the study of memory, then the reader might well suppose that this chapter will be very brief. Well, do not get your hopes up. In recent years the number of relevant studies has increased dramatically, reflecting psychologists' increased interest in culture. A simple search using PsycINFO and the key words *culture* and *memory* indicates that studies assess-

ing culture and memory were rare until the 1980s, with a dramatic rise in the early 1990s (Figure 26.1). We begin our analysis of this literature by explaining what we mean by the term "culture."

Concurring with Bartlett and others (e.g., Bruner, 1990; D'Andrade, 1992; Holland & Quinn, 1987; Valsiner, 2000; Vygotsky, 1978; Wang & Brockmeier, 2002), we view culture as both a system (values, schemas, scripts, models, metaphors, and artifacts) and a process (rituals, daily routines, and practices) of symbolic mediation. By operating on social institutions (e.g., the family) as well as on the actions, thoughts, emotions, and moral values of individuals, culture regulates both intrapersonal and interpersonal psychological functions. Through socialization, individuals acquire knowledge and competencies that serve culturally prescribed goals. Similar to other abilities, memory is useful to the extent that it helps people achieve their objectives. We assess whether culture affects why people remember, how people remember, when people remember, what people remember, and whether they judge remembering to be necessary at all.

We focus on a particular type of memory, autobiographical recall. Autobiographical memory refers to memory for personal experiences. Autobiographical memories often include de-

FIGURE 26.1. Number of publications in 5-year time bins of articles with any mention of culture and memory (from the PsycINFO database).

tails of what happened, who was involved, and where and when the episodes occurred (Tulving, 2002). A great deal of research on memory and culture concerns autobiographical memory. Our discussion reflects this reality. We adopt a functional approach to examine cultural emphases on different goals and functions of autobiographical remembering. We show that such cultural differences have important consequences for the content, style, emergence, and general accessibility of autobiographical memories.

FUNCTIONS OF REMEMBERING

According to Neisser (1982), the primary task of memory researchers is to understand “how people use their own past experiences in meeting the present and the future,” a task that has to be carried out in different settings “because changes in the social and cultural environment can change the uses of the past” (p. 12). Throughout human history, an accurate memory probably has provided an evolutionary advantage. At a basic survival level, a good memory could help individuals find food and avoid danger. Furthermore, ecological factors often encourage the development of particular memory skills. For instance, Australian Aboriginal children and adolescents of the desert regions develop extraordinary visual-spatial memory that enables them to navigate in their physical surroundings (Kearins, 1981, 1986). Social factors also play an important role. In New Zealand, Maori adults, who grew up in a culture with a strong oral tradition, develop an enhanced ability to remember events from the remote past (MacDonald, Uesiliana, & Hayne, 2000). More generally, people become skilled at remembering information important to their everyday activities.

In all cultures, verbatim or precisely accurate memory is necessary in some contexts. In Western classrooms, children memorize both poems and the multiplication tables. Eight times eight is precisely 64. Sixty-three and 65 are wrong, despite their proximity to 64. Similarly, religious texts are often memorized by their devotees. In most contexts, however, children and adults are not required to produce a verbatim memory. Daily remembering typically involves recalling the meaningful gist of episodes rather than exquisite detail. For example, if a friend asks about your lunch, you might report eating

a hamburger and salad at the local diner. Your friend is probably not interested in knowing the exact contents of your salad; whether the hamburger bun had seeds; other items on the menu and what they cost; the precise time at which you ate; the specific booth you occupied; the number of other customers and what they had for lunch; the name, height, and weight of your server; the number of restaurant personnel and their genders; the location of the cash register and safe; and so forth. Even if your friend were interested in such details you would probably not be able to provide all of them. For example, we seldom pay sufficient attention to our servers to be able to distinguish them from other servers in a restaurant.

What constitutes meaningful gist, however, is highly dependent on a person’s goals (Conway & Pleydell-Pearce, 2000). Suppose that your primary goal on entering the restaurant was to case the joint to plan a robbery with your friend. You would then notice and recall quite different information (Anderson & Pichert, 1978), including perhaps the number and genders of the personnel, and the location of the cash register and safe. People’s goals and memories vary with their personal concerns. More important from this perspective, people’s goals and memories vary in response to their social context and culture.

Different cultures champion different views of the very concept of memory. The Indian Buddhist conception of memory (*Smriti*) includes factors of apperception or awareness of object (*Phassa*), perception (*Sanna*), insight (*Panna*), and mindfulness (*Sati*) (Deshpande, 1996). This Buddhist perspective is different from both classical and more modern Western views of memory. Discussions of memory in classical and medieval Western writings focus on image, impression, storehouse, and recollection; modern empirical approaches emphasize encoding, recall, and recognition (Carruthers, 1990). According to Buddhism, memory during waking states (*Abhavitā-Smar-tavyā*) is the creation of God. Also, certain mental states, such as that achieved during meditation, enable individuals to remember everything, including events from previous lives. Whereas modern psychologists tend to ascribe the loss of memory to encoding and retrieval failures or to neurological dysfunction, Indian Buddhist scriptures attribute forgetting to daytime naps or too much alcohol. A person who sleeps during the day or consumes alcohol suffers from in-

creased *Kafa* and *Pitta* and “cannot obtain any clear knowledge, philosophical [or] otherwise” (Deshpande, 1996, p. 63). To improve memory, Indian Buddhist thinking advocates that individuals free themselves from lust, anger, delusion, and egoism. In contrast, Western models of memory emphasize the use of memorial strategies to improve recall. Differing cultural beliefs about memory are likely to affect how and when people use memory. We focus on a number of different intrapersonal (self-defining, directive, self-enhancing, and emotional expression) and interpersonal (e.g., relationship maintenance) functions of autobiographical memory, and discuss findings for other types of memory for which relevant data are available.

INTRAPERSONAL FUNCTIONS OF AUTOBIOGRAPHICAL MEMORY

Self-Definition

According to Western intellectual tradition, self-definition is perhaps the most important intrapersonal function of autobiographical memory. Memory is assigned a central role in the development, maintenance, and expression of an enduring self-concept (Bruner, 1990; Brockmeier & Carbaugh, 2001; Hume, 1739/1882; James, 1890/1950; McAdams, 1993; Nelson, 1996; Pillemer, 1998; Ross, 1989; Singer & Salovey, 1993). In a *Treatise on Human Nature*, Hume (1739/1882, p. 542) proclaimed the importance of autobiographical memory: “Had we no memory, we never should have any notion . . . of that chain of causes and effects, which constitute our self or person.” From this perspective, people establish the meaning, purpose, and value of their existence by recollecting and identifying with their past selves (Antze, 1996; Herman, 1992; Lowenthal, 1985). They mine their pasts to establish both who they are and who they are not. For example, a mathematician who is confident of her own intellectual attainment might remember the thrill of past successes, such as winning competitions and receiving awards. She may also remember a few disconfirming episodes, such as failing a high school algebra class. She might rationalize such incidents by attributing poor performances to immaturity, and thereby maintain her current (mature) identity as an accomplished mathematician (Wilson & Ross, 2001). To some extent, “the

sureness of ‘I was’ is a necessary component of the sureness of ‘I am’ ” (Wyatt, 1963, p. 319).

This emphasis on using personal memory to define one’s self-identity may be intimately linked to the Western conception of selfhood, which focuses on autonomy and independence. The self is a unique collection of inner attributes, qualities, dispositions, and opinions (Fiske, Kitayama, Markus, & Nisbett, 1998; Geertz, 1973; Kağitçibaşı, 1996; Markus & Kitayama, 1991; Shweder et al., 1998; Triandis, 1989). By helping individuals to distinguish themselves from others, memories of distinctive personal experiences serve as an important and even necessary component of an independent self-construal. To a Western reader, this emphasis on the importance of autobiographical memory for self-identity might seem to be an obvious truism. Otherwise how could you “know” yourself?

Yet in many other cultures, such as those in East Asia, autobiographical memory is not central to self-identity. In these cultures, an interdependent or relational self-construal is defined largely by an individual’s place within his or her network of relationships (Fiske et al., 1998; Kağitçibaşı, 1996; Markus & Kitayama, 1991; Shweder et al., 1998; Triandis, 1989). Social status and roles, such as memberships in the family, the workplace, religious groups, or the nation, are crucial constituents of self and identity. In this context, autobiographical memories seem not to be particularly important to individuals. Wang and Conway (2004) reported that European American middle-aged adults rated their autobiographical memories as more personally important to them than did Chinese, regardless of the life period in which the events occurred. Sankaranarayanan and Leichtman (2000) observed that their rural Indian informants had great difficulty when asked to report memories of childhood experiences. They often appeared puzzled and even annoyed, asking, “Why would one want to remember such things?” In an even more striking case, anthropologist Röttger-Rössler (1993) was unable to collect autobiographical stories in a rural Indonesian community: “Not one villager was willing to speak about his or her own life, not even some episodes of it” (p. 366). Despite their close relationship with the researcher, villagers felt uncomfortable and embarrassed when asked to talk about themselves. When they spoke about personal experiences in everyday conversations, their accounts were

“event-centered.” According to Röttger-Rössler, “it is almost impossible to learn something about the feelings and emotions of the narrator” (p. 366). In contrast, Western respondents often seem happy to provide self-revealing accounts of their own lives.

The varied cultural emphases on the self-defining value of autobiographical memories are reflected in people’s ability to recall very long-term memories, such as their earliest childhood experiences (MacDonald et al., 2000; Mullen, 1994; Wang, 2001a). Although adults from all cultures are typically unable to recall events from their first years of life (Pillemer & White, 1989), there are cultural differences in the accessibility of early memories. In general, when people are asked to relate their earliest childhood memory, the earliest events recalled by adults of European descent originally took place, on average, at about 3½ years of age; in contrast, the earliest childhood events recalled by participants of Asian heritage occurred between 6 and 17 months later (MacDonald et al., 2000; Mullen, 1994; Wang, 2001a). In a recent study, researchers examined adults’ general ability to access memories of early childhood in the United States (all European Americans), England, and China (Wang, Conway, & Hou, 2004). Participants were asked to recall as many events occurring before the age of 5 years as they could within 5 minutes. U.S. participants recalled the greatest number of childhood memories ($M = 12.24$), followed by British participants ($M = 9.83$), and then Chinese ($M = 5.68$). Consistent with other studies, the earliest childhood memories of Chinese participants were approximately 6 months later than their Western counterparts. Although it is possible that participants’ memories of early childhood events are affected by photos they have seen or stories they have heard, researchers studying early memories attempt to focus on events participants remember independently of external sources.

What are the bases of these early memory differences? Conceivably, cultural conceptions of selfhood guide remembering (Mullen, 1994; Wang, 2001a; Wang et al., 2004). An autonomous self-view might motivate individuals to attend to, encode, ruminate, and talk about significant personal experiences. These experiences should help individuals to distinguish themselves from others and reaffirm their independence and unique identity. Consequently, individuals’ cognitive resources may be chan-

neled into the early development of an organized, articulated, and durable autobiographical memory system. In contrast, the relational self-view associated with many Asian cultures might instead promote the retention of knowledge critical for social harmony and collective solidarity. The development of a structured autobiographical memory system may not be accentuated in this context.

It is obviously an overgeneralization to presume that all Westerners have an autonomous view of self and all Easterners have a relational view of self. Regardless of culture, most people will perceive themselves as possessing both relational and personal aspects. In Eastern cultures, relational qualities should predominate on average, but the degree to which this is the case will vary across individuals and circumstances (I. Choi, Nisbett, & Norenzayan, 1999; Hong, Morris, Chiu, & Benet-Martinez, 2000; Mascolo & Li, 2004; Voronov & Singer, 2002). Similarly in Western cultures, personal traits should predominate on average, but the balance of personal and relational traits in self-views will vary across individuals. To test the association between the autonomous-relational dimension of the self and autobiographical memory, Wang and colleagues (Wang, 2001a; Wang, Leichtman, & White, 1998) examined self-descriptions and earliest childhood memories in European American and Chinese young adults. In both cultures, participants who focused on personal unique attributes in their self-descriptions tended to report earlier and more detailed childhood memories than did participants who focused on social roles and categories in their self-descriptions.

If individuals view themselves as possessing both personal and relational aspects, it ought to be possible to prompt them to focus temporarily on either their relatively unique personal self or their relational self (Trafimow, Silverman, Fan, & Law, 1997). Wang and Ross (2005) showed that such shifts in attention can affect the accessibility of early memories. European and Asian American participants were asked to describe themselves as either a unique individual (personal prime) or as a member of various social groups (relational prime) prior to recalling their earliest childhood memory. The personal prime increased the accessibility of earlier first memories among Asians, such that they reported their earliest childhood memories from approximately 3½ years of age,

just as European Americans did. European Americans were unaffected by the prime, presumably because they had accessed the earliest memories possible in this experimental paradigm (Mullen, 1994; Pillemer & White, 1989; Wang, 2006).

Previous findings that first memories of Asians are later than the first memories of Westerners would seem to reflect a stable cultural difference: Asians cannot retrieve earlier memories because they do not have such recollections in their memory store. However, the Wang and Ross (2005) priming study suggests the intriguing possibility that cultural disparities reflect differences in memory *accessibility* rather than memory availability. In general, childhood memories recalled from an early age tend to focus more on the self and less on others than do those from an older age (Wang, 2001a). Consequently, it makes sense that a personal prime provides a cue that enables Asians to access earlier first memories than they normally would. It would be making too much of a single study, however, to argue that cultural differences in the age of earliest recall are *entirely* due to memory accessibility rather than availability. More research along these lines is needed.

The impact of culture on memory goes far beyond the age of earliest memories. The divergent modes of self are associated with different genres of autobiographical remembering, as reflected in the style and content of memory recall. One intriguing cultural difference in autobiographical remembering concerns whether people report specific (e.g., “the time I fell in a pond”) or generic memories (e.g., “often playing with other kids in the woods”). Differences in the specificity of autobiographical memories may reflect cultural variation in the nature of self and identity. Specific episodes are often personal experiences that could promote a unique, autonomous sense of self. Generic memories might imply the importance of social conventions, as well as emphasize an individual’s relation to significant others and the community. As a result, generic memories could contribute to a relational sense of self.

Studies of children’s autobiographical memories reveal cultural differences in the specificity of recall. American preschoolers reported a greater proportion of specific autobiographical memories than did their same-age Korean and Chinese counterparts (Han, Leichtman, & Wang, 1998; Wang, 2004a). Minami and

McCabe (1991) interviewed Japanese and American children ages 6 to 9 years about past injuries. Japanese children tended to speak of collections of experiences rather than focusing on any one particular injury, despite being repeatedly prompted to talk about a single episode. In contrast, North American children tended to talk about one specific injury at great length. Cultural differences in memory specificity, evident in the preschool years, persist into adulthood. Both Western and Asian adults produce specific memories, but the tendency to do so is consistently stronger among Westerners (Wang & Conway, 2004; Wang, 2006).

Different cultural views of the self are even related to individuals’ memory imagery. Asian Canadians are more likely than European Canadians to adopt a third-person (as opposed to a first-person) perspective on themselves when recalling events in which they were the focus of other people’s attention (Cohen & Gunz, 2002). In a third-person perspective, individuals see themselves in the scene, as if viewing themselves through the eyes of a bystander (e.g., they see themselves talking in front of an audience). Conceivably, recalling personal events from the perspective of an audience serves as a reminder that one should behave properly and conform to group standards. Such norms are clearly defined and emphasized in Asian cultures, where the self is regarded as fundamentally interconnected to significant others rather than as an autonomous entity.

In a related vein, memory *content* also appears to vary with culture. From an information-processing point of view, an autonomous, independent self-construal may lead individuals to attend to event information relevant to their own roles, actions, feelings, and predilections. Such information is likely to be well represented in memory and highly accessible during recall. In contrast, an interdependent self-construal might enhance attentiveness to collective activities and significant others, with the result that such relational information is readily accessible during recall. Consistent with this analysis, researchers have reported systematic cross-cultural differences in the content of autobiographical memories (Mullen, 1994; Wang, 2001a, 2006; Wang & Conway, 2004; Wang & Ross, 2005). European Americans often provide memories of unique personal experiences (successes, failures, fears, nightmares, etc.), with frequent descriptions of emotions, personal opinions, and self-

determination. Conversely, native Chinese and Asian Americans often report memory events that are focused on group actions and interpersonal relations (school activities, family outings, disputes with neighbors, etc.). Such differences are also observed among preschool-age children. European American youngsters tend to report more detailed, emotional, and self-focused accounts of personal experiences than do their Asian peers (Han et al., 1998; Wang, 2004a; Wang & Leichtman, 2000).

The impact of an autonomous versus relational sense of self on memory extends to remembering lists of words. Wagar and Cohen (2003) asked university students to relate words in a list to the self ("Does the word describe you?") or to a friend ("Does the word describe your best friend?"). The words either represented personal qualities (happy, generous, etc.) or social roles (brother, roommate, etc.). Later, participants were shown a list of words, including some words from the previous list and some new words. Participants were asked to identify the words correctly as new or old. Asian Canadians identified collective traits encoded in relation to the self most quickly and personal traits encoded in relation to the self most slowly. Wagar and Cohen suggested that these results indicate that the self-concept of Asian Canadians consists chiefly of social role traits: "When collective traits were encoded into a schematically rich collective, long-term self, strong memory traces were formed" (p. 472). European Canadians showed a standard self-reference effect (Rogers, Kuiper, & Kirker, 1977). They more quickly recognized words originally encoded in relation to self than in relation to their best friend, regardless of trait type.

Autobiographies provide an example of how cultural views of self influence memory content. Traditional Chinese autobiography imitated biography almost "slavishly" (Wu, 1990). Authors usually reported public and official events, and seldom disclosed their inner emotions or motives. Even when writing about unique personal experiences, such as adventures in foreign lands, autobiographers focused on facts about the places they visited rather than on their own "inner life," such as their thoughts and feelings. Wu suggested that using the format of biography to tell a personal story might protect the autobiographer "from the censure of egomania, of doing something unconventional" (p. 3). It is also possible that

Chinese autobiographers fail to report personal details because they are less accessible: Research on cultural differences in autobiographical memory suggests that the recollections of Chinese autobiographers would be less self-focused than the memories of Western autobiographers, even if the memory reports were private and confidential (as is the case in psychological research). Although autobiography has evolved as an independent literature genre in China, contemporary Chinese autobiographical writings still lack self-focus in comparison to their European and American counterparts (Pillemer, 1998).

The commitment to a unique individual self is highlighted in the first modern (Western) autobiography—Rousseau's *Confessions* (1782/2000, p. 5):

I am resolved on an undertaking that has no model and will have no imitator. I want to show my fellow-men a man in all the truth of nature; and this man is to be myself. Myself alone. I feel my heart and I know men. I am not made like any that I have seen; I venture to believe that I was not made like any that exists. If I am not more deserving, at least I am different. As to whether nature did well or ill to break the mould in which I was cast, that is something no one can judge until after they have read me.

Baumeister (1987) provided another perspective on the relation between self-views and autobiography. He reviewed the scholarly literature on changes in Western beliefs about the self from the 11th through the 20th centuries. The Western notion of an inner self that is distinguishable from appearances and public actions did not emerge as a widespread belief until about the 16th century. Moreover, it was only in the 19th century that "personality (rather than social rank and roles) came to be increasingly regarded as a, even *the*, central aspect of the self" (p. 166). Most interesting for this analysis, this 19th century shift in views of the self is accompanied and evidenced by trends in autobiographical writing, which began to highlight personal information. In addition to supporting the association between self-views and autobiography, Baumeister's review indicates that self-knowledge reflects the relation of the individual to society. When societies change, self-views change, and so does autobiography.

In related research, Dekker (2000) examined transformations in "egodocuments," including

diaries, autobiographies, and other forms of personal records, from the Golden Age to Romanticism (17th–19th centuries) in Holland. Before 1800, a standard personal record contained extensive descriptions of family background. The individual was depicted primarily as a link in a family tree. A new type of record emerged around 1800. Authors began to dwell on their childhood, and the self became the center of their text. Egodocuments also came to be an important outlet for expressing personal feelings. These changes reflect the growing individualism during this historical era in Holland, and the shifts in social conventions with regard to emotions and ideas about children.

Psychologists do not tend to study history, but they can use the tools of experimental psychology to produce individual shifts in autobiographical remembering that might take generations or even centuries to occur at a societal level. If historical and cultural variations in autobiographical memory are due to differing self-views, then people who regard themselves primarily in terms of personal traits should exhibit a more Western style of autobiographical memory regardless of their culture: Their autobiographical memories should be detailed, specific (rather than generic), and self-focused. In the Wang and Ross (2005) priming study described earlier, the personal prime elicited memories that focused more on the rememberer and less on social interactions than did the relational prime, regardless of culture. Psychologists also study individual differences in self-views within a culture. Regardless of cultural group, children and adults who dwell more on personal attributes and predilections when describing themselves are also more likely to provide self-focused, specific memories compared to those who dwell more on social roles and group memberships when describing themselves (Wang, 2001a, 2004a).

It is important to keep in mind that cultural variations in memory may reflect different processes at every stage of remembering, from perception and meaning analysis to retention and recall. Compared to European Americans, East Asians attend to, perceive, and retain more contextual information and relationships in their environment (Masuda & Nisbett, 2001). They also refer more to the context or the group when explaining physical and social phenomena (Chiu, Morris, Hong, & Menon, 2000; I. Choi et al., 1999). Not all information that people notice is preserved in long-term

memory, however, as anyone who has studied for an examination can testify. Information is more likely to be retained if it is consolidated with preexisting cognitive frameworks, such as views of self (Anderson & Pichert, 1978; Bartlett, 1932; Rogers et al., 1977). Finally, people's goals and beliefs at the time of retrieval, including their culturally shared beliefs and self-views, influence which elements of the retained information they access, as well as how they build on that information to construct an autobiographical memory (Bartlett, 1932; Neisser, 1967; Ross, 1989).

Directive Function

Regardless of culture, people rely on autobiographical memory to guide many of their everyday decisions. In selecting a toy from a bin, a book from a shelf, or a favorite food from a menu, children and adults may refer to memories of their previous experiences. In addition to guiding mundane actions, memories play a major role in Eastern and Western moral and religious traditions. According to Confucian ethics, people should engage in daily recollections of their actions, examining their behavior on three dimensions: Have I done my best for others? Have I been trustworthy in my dealings with friends? Have I failed to revisit what the Master has taught me? This practice of autobiographical reflection (*zi-xing*, 自省) is considered essential for an individual to achieve the Confucian fundamental value, *ren* (仁), the supreme virtues of benevolence, moral vitality, and a sensitive concern for others.

Memory plays a directive role in Western religious traditions as well. In his *Confessions*, St. Augustine analyzed memory to achieve a greater understanding of himself and God. Also, by documenting and publicizing how he changed from a wayward youth to a wise man of God, he hoped to inspire others to do the same. More directly comparable to Confucian self-examination is the Examen, a centuries-old feature of Catholic spirituality that involves a retrospective analysis of one's thoughts and actions on a daily basis. During the Examen, individuals review their entire day in detail, recalling what happened and how they acted. When and why did they act badly (e.g., become cross with someone)? When and why did they behave correctly (e.g., aid an elderly person)? They apologize to God for their faults, thank God for their virtues, and pray that God will

guide them in the right direction in the future (Catholic Update, March 2003).

Along the same lines, Jewish tradition dictates that, during the “Days of Repentance” that conclude with Yom Kippur, Jews recall their misdeeds of the previous year, identifying sins that they have committed against the laws of God and sins against persons. They can appease God through prayer, confessing their sins and asking for forgiveness. To atone for sins against another person, they must first seek reconciliation with that person. Individuals who succeed in repenting their sins are granted a good and happy new year.

There are similarities and differences between the directive functions of autobiographical memory in Eastern and Western moral and religious traditions. In each case, self-improvement is an important goal. The major cultural difference concerns the focus of the improvement. Confucian ethics, adopted by many Eastern traditions, emphasize the importance of interdependence and maintaining good relationships with other people. A focus on relationships with others is also important in Western religious traditions, but an even greater concern is people’s individual relationship with their God and the implications of this relationship for their own well-being.

Although autobiographical memory serves a directive function in Western cultures, it might play a greater role in Eastern cultures. Wang and Conway (2004) found that when recalling personal experiences across the lifespan, Chinese middle-aged adults were more likely than their European American counterparts (48% vs. 9%) spontaneously to generate mores, worldviews, and behavioral lessons from the memory events. Examples include “Since then, I have realized that there are more nice people than bad ones in this world,” and “I learned that perfection takes practice.”

In the Confucian intellectual tradition, “learning implies full knowledge of the precedents of a past age” (Nakamura, 1964, p. 205). This emphasis on the accumulation of knowledge to understand the world produces a positive and trusting attitude toward the past, as exemplified in the often-observed tendency to take ancient wisdom for granted (Lin, 1939). This acceptance is in direct contrast to the Western tradition that encourages independent thinking. Existing ideas and theories are questioned, developed, and overturned rather than memorized exactly (Tweed & Lehman, 2002).

An intriguing illustration of this cultural difference concerns the practices of magicians in China and North America. In a documentary broadcast on Canadian television in 2001, American magicians Penn and Teller visited China to observe and exchange tricks with local magicians. Penn and Teller were surprised to discover that Chinese magicians pride themselves on learning to reproduce tricks exactly as their masters have shown them. In contrast, North American magicians favor putting a new spin on an old trick (Bienstock, Grogan, & Smith, 2003). Thus, the different intellectual values assigned to the past can affect how individuals in diverse cultures use memories to direct their activities.

Individuals in Western cultures do report using their memories to guide their behaviors in some contexts. Pillemer (1998) analyzed an 8-year-old child’s memory of being kidnapped at gunpoint and the horrifying lessons the memory contained about which situations are dangerous and to be avoided. Memories of more common life episodes can also contain guidelines for current and future actions. For example, a college student reported that she learned an important lesson about planning after a miserable trip; a football captain reported using memories of previous losses to motivate his team members; and individuals often described past advice offered by parents or teachers (Pillemer, 2003). Webster and colleagues (Webster, 1993, 1997; Webster & Cappeliez, 1993) developed a 43-item Reminiscence Functions Scale, in which participants indicate on a 6-point scale how often they reminisce with a particular function in mind. On the basis of responses to this scale, the researchers identified two autobiographical memory uses closely related to directive functions: problem solving (remembering past problem-solving strategies for the present purpose) and teach/inform (using reminiscence to relay instructional information to others).

It is unclear whether people’s subjective reports about the functions of memory reveal how they actually use their memories in everyday life. For example, people’s answers on the Reminiscence Functions Scale might reflect their understanding of how memory *should* be used in their culture. Similarly people might claim to remember and respect the advice of their parents—but do they act on the advice? To study whether people actually use their autobiographical memories as a guide, research-

ers need to examine directly whether people draw on their recollections while making judgments and decisions.

In one relevant set of studies, researchers examined people's estimates of when they would finish a project (e.g., a school assignment or household renovation). It seems obvious that autobiographical memory could be useful in predicting task completion times. If people want to estimate how long it will take to renovate a kitchen, they should try to recall their own or others' past renovations. Yet individuals in Western cultures often neglect information about past experiences when predicting task completion times (Buehler, Griffin, & Ross, 1994, 2002; Kahneman & Tversky, 1979). People frequently base their predictions on their intentions and hopes rather than on their own or others' previous experiences. As a consequence, they are too optimistic, a phenomenon that Kahneman and Tversky labeled "the planning fallacy."

Do East Asians exhibit a similar disdain for memories of past experiences while estimating task completion times? The answer is apparently "yes." Buehler and his colleagues (Buehler, Otsubo, Lehman, Heine, & Griffin, 2004) found that Japanese participants were as likely as their Canadian counterparts to underestimate their task completion times and to ignore past experiences when making predictions. At least in this context, there is no evidence that East Asian university students make more use of the past to guide their predictions than do Canadian university students.

Prediction is about the future and may orient people away from the past. It seems likely that research in other decision-making domains will provide more convincing evidence of the directive function of autobiographical memory. Regardless, the prediction research suggests the value of studying directly how people use memory to guide their judgments and decisions. Until there is more research of this sort, whether or to what degree there are cultural differences in the directive functions of memory is still an open question.

Self-Enhancement

A great deal of social-psychological research on Western participants supports the idea that individuals are often motivated to think favorably about themselves. Wilson and Ross (2001) have shown that people can use autobiograph-

ical memories to support positive self-conceptions. In one set of studies, people evaluated their current selves (what they are like now) more favorably than they evaluated their past selves (what they were like several years earlier). While not denying that people can improve, Wilson and Ross observed that the retrospective criticism of past selves was often overly harsh and seemed to be motivated by a desire to enhance the current self. Individuals can be relatively pleased with their present selves, if they regard it as superior to their former selves. Even when they do not judge themselves to be perfect now, they can derive self-satisfaction by presuming that they are more mature, hardworking, and socially skilled now than they used to be.

Several studies have provided evidence that retrospective self-criticism is motivated by concerns for self-enhancement and does not simply reflect actual self-improvement (Wilson & Ross, 2001). For example, derogation of past selves is especially evident on important traits, occurs for self-appraisals but not for ratings of acquaintances, is more pronounced among high than among low self-esteem individuals, and occurs even when concurrent ratings imply that no actual improvement has transpired.

Ross and Wilson (2002) described a second way in which people use autobiographical memory to maintain or enhance positive self-regard. They asked participants to remember past incidents that reflected either favorably or poorly on themselves. They then asked participants to report how far away in time the incidents felt (e.g., *feels like yesterday* vs. *feels far away*). Participants reported feeling farther away in time from earlier experiences with unfavorable implications for their current self-views than from equally distant experiences with flattering implications. For example, participants who performed poorly in a course felt more distant from the course than did participants who performed well. This asymmetry in subjective time estimates occurs even when participants are first reminded of the exact date of the episode. According to Ross and Wilson, the asymmetry reflects the motivation to maintain favorable self-regard. By subjectively distancing an unflattering episode, individuals can attribute it to an inferior, earlier self and dissociate their current self from blame. In contrast, people can continue to claim credit for former accomplishments by feeling temporally close to such episodes.

The Wilson and Ross studies were conducted on Western participants. The use of memory to facilitate favorable self-appraisals contradicts a primary purpose of remembering in Confucian cultures. East Asians are exhorted to use memory as a means of attaining self-criticism and self-reflection (Wang & Conway, 2004). From this cultural perspective, individuals should use memory to attain actual self-improvement rather than the more illusory self-enhancement that seems to gratify Western participants. Therefore, East Asians should not derogate past selves to feel good about their current selves; nor should they feel farther away in time from unflattering episodes than from equally distant pleasing episodes. Recently, researchers obtained these very results (Ross, Heine, Wilson, & Sugimori, 2005) when they replicated the two memorial biases in Canadian samples but found these same biases to be absent in Japanese samples.

Just as people can use memory to support favorable views of themselves, they can also use it to maintain favorable views of their relationships and, consequently, their relational self. Karney and his associates (Karney & Coombs, 2000; Karney & Frye, 2002) found that Western participants' retrospective evaluations of their marriages followed a pattern that echoed the findings of Wilson and Ross for individual recall. Spouses remembered their earlier marital satisfaction as lower than their present satisfaction, even when it was actually higher (as evidenced by their actual ratings at the earlier time period). By underestimating their former satisfaction levels, individuals can create the illusion of marital improvement in the face of decline.

Other memory biases also help people maintain favorable evaluations of current relationships. Research on Western participants reveals that dating partners interpret past conflicts in a relationship-enhancing fashion. In a recent study, dating couples were asked to recall a conflict in which one partner was the perpetrator and the other was the victim (Cameron, Ross, & Holmes, 2002). Transgressions committed against intimates threaten a perpetrator's self-regard, as well as the happiness and security of a relationship. Consequently perpetrators should be particularly motivated to downplay the negative consequences of their actions. Relative to their victims, perpetrators described their actions as more justifiable and perceived greater improvement (in themselves,

their victims, and the relationship) since the time of the transgression. Perpetrators were also more optimistic about the future of their relationship. Ironically, perpetrators were more confident that their relationship would persist than were control participants who were not asked to recall any transgression.

The studies by Karney, Cameron, and their respective associates were conducted with North American participants. We are unaware of any similar studies of participants from non-Western cultures. If the studies of intrapersonal memory biases serve as a reliable guide, then we should expect studies of East Asian participants to reveal less evidence of relationship-enhancing memory biases. Relative to Western participants, East Asians should be more interested in learning from past problems and achieving genuine rather than illusory relationship improvement. Alternatively, given their cultural emphasis on interpersonal harmony and a relational self-construal, East Asians might exhibit similar or even greater memorial biases to enhance their significant relationships.

Emotional Expression and Memory

There is an extensive literature on similarities and differences across cultures in the experience, expression, and determinants of emotion (e.g., Kitayama & Markus, 1994; Oishi, 2002). Our purpose, rather than to review this research, is to examine the role of memory. Much of the research on emotion is retrospective in nature. For example, people are asked how frequently they felt various emotions in the last month (e.g., Eid & Diener, 2001). Such reports are retrospective constructions that can provide valuable information about people's beliefs and schemas. However, such constructions might or might not accurately characterize the original emotional experiences. Perhaps it is not surprising, then, that retrospective reports have been shown to be both accurate, in the sense that recollections are correlated with earlier online reports of mood (e.g., Feldman Barrett, 1997), and also biased by the rememberer's personality and beliefs about emotional experiences (Christensen, Wood, & Feldman Barrett, 2003; Feldman Barrett, 1997; Robinson & Clore, 2002).

Doubts about the accuracy of recalled emotions are particularly significant when researchers use recall as the basis for claiming

cross-cultural differences in emotional experience. When asked to remember their past emotional experiences, European American and Canadian participants recall experiencing many more positive (e.g., happy) than negative emotions (e.g., sad) in their everyday lives. In contrast, samples of East Asian Americans and Canadians, as well as participants living in Japan, report experiencing about the same number of positive and negative emotions (Markus & Kitayama, 1994; Oishi, 2002; Ross, Xun, & Wilson, 2002). The cultural discrepancy appears to be especially strong for positive emotions: European Americans and Canadians recall experiencing positive emotions more frequently than do Asians. Along the same lines, surveys indicate that Japanese respondents report being less satisfied with their lives as a whole than do their counterparts in North America and Western Europe (e.g., Diener, Diener, & Diener, 1995; Kitayama, Markus, & Kurokawa, 2000; Veenhoven, 1993).

These research findings can be interpreted as indicating that Westerners experience a greater frequency of positive emotions on a daily basis than do their East Asian counterparts. Alternatively, perhaps Western and East Asian individuals experience about the same number of pleasant and unpleasant episodes, but Westerners recall a greater number of their pleasant experiences. Such a recall bias in Western cultures could reflect a cultural schema that happiness is important and common (Oishi, 2002). If this positive outlook is less evident in East Asia, then Westerners and East Asians might recruit memories that support their differing beliefs, with the result that Westerners recall more happy experiences.

Oishi (2002) compared retrospective accounts of emotion to daily diary and online reports of emotional experiences. He found that European and Asian Americans did not differ in daily diary reports of the quality of their day, or in online reports of current positive (e.g., pleasant, calm, happy) and negative moods (e.g., unpleasant, sad, worried). Interestingly, cultural differences clearly emerged at the end of the week, when participants were asked how good or bad the week was, or how often they had experienced different positive and negative moods. European Americans retrospectively reported greater satisfaction with the week and a higher frequency of positive emotions. Note that Asian Americans did not report a higher frequency of negative moods than did Euro-

pean Americans. Asians do not appear to accentuate the negative; they simply dwell less on their positive experiences than do their Western counterparts when recalling the past.

Oishi's (2002) data also raise a more profound question. Are East Asians truly less happy than their Western counterparts? The answer to this question depends on whether one focuses on current or retrospective reports. Certainly a good case could be made for the importance of memory: A current emotional experience is fleeting, whereas memory can be more enduring. As Oishi observed, "Retrospective judgments seem to be as important as actual experiences in understanding subjective experiences of well-being. . . . Online and global reports capture different but equally important aspects of well-being" (p. 1405).

Oishi's (2002) study is unlikely to be the final word on whether cross-cultural differences in emotional experience reflect retrospective biases or online differences in emotional experience. Other researchers using different samples and procedures might well find evidence of online differences. From our own perspective, the Oishi study is important for two reasons. First, it reminds us yet again that recall should never be assumed to be an exact replica of earlier experience—recall is a reconstruction of the past. Second, Oishi showed that retrospective reports can be psychologically significant even when they do not mirror online reports. As well, retrospective reports provide valuable information about cultural similarities and differences in people's beliefs and feelings.

INTERPERSONAL FUNCTIONS OF AUTOBIOGRAPHICAL MEMORY

Remembering is a private experience. Only rememberers can directly know their own thoughts and feelings. However, individuals often share reminiscences with each other, so remembering can be a social exchange as well. In conversations, people may invoke their memories of past occurrences to achieve a host of goals, including education, entertainment, mutual understanding, improved social bonds, and emotional regulation (Bluck, 2003; Pasupathi, 2001; Robinson & Swanson, 1990; Ross & Holmberg, 1990; Webster, 1997). Although the nature and frequency of conversations reflect the general norms of discourse in a culture, variations in sharing memory may also

reveal how people interpret and remember events. As well, conversations about the past can further shape people's subsequent memories of the episodes.

Cross-cultural researchers have tended to focus on parent-child memory conversations (S. H. Choi, 1992; Miller, Fung, & Mintz, 1996; Miller, Wiley, Fung, & Liang, 1997; Minami & McCabe, 1995; Mullen & Yi, 1995; Wang, 2001b). This research is of particular interest, because theorists have argued that memory conversations between parents and children play a critical role in the development of autobiographical memory (see Nelson & Fivush, 2004). We begin our discussion of memory conversations by focusing on cultural variations in the interpersonal functions of memory and the associated differences in conversational styles and content. We then discuss memory conversations and their developmental implications for children's own memory operations.

Relationship Maintenance

Memory conversations permit individuals to sustain and enhance their relationships in a relatively effective and effortless manner. Sharing personal memories with others can elicit empathic and emotional responses that can serve to deepen intimacy between the conversational partners. As a result, such conversations are considered a valuable social practice in Western cultures (Fivush, 1994; Nelson, 1993; Pasupathi, 2001; Pillemer, 1998). This interpersonal function of memory seems to take a different form in East Asian cultures. Relationships among individuals are defined primarily by existing social orders and are thus less voluntary (Bond, 1991; Markus & Kitayama, 1991; Shweder et al., 1998; Triandis, 1989). Memory conversations in Eastern cultures tend to define and reinforce an individual's duties, obligations, and appropriate behavior, as well as to establish his or her position in a relational hierarchy.

The use of memory sharing to maintain positive relationships in Western cultures is illustrated in this European American mother's account of when and why she usually shared memories with her 4-year-old son (Wang, 2006, unpublished raw data):

Every night at the dinner table, we talk about what happened during the day. We ask what happened during the day, whom he played with, what

was the best thing about the day. Also I ask if anything made him sad during the day. Sometimes, about once a week, at bedtime I tell Jake memories about when he was a baby, things he did. He loves that. Jake always also loves to hear about memories of what my husband & I did when we were young. About once a month we get out videotapes of family trips that we've taken, that Jake has been on. That seems to be boring for the kids; they prefer talking about the vacation and remembering that way instead. We talk about happy memories usually. Sad or bad memories we normally only talk about if we're trying to say, "this happened last time, we don't want to have it happen again," like having to leave a restaurant for bad behavior. I share good memories, memories of times that I know Jake enjoyed, to see him smile, to share a happy moment remembering, to think of happy experiences that we might want to do again.

Accordingly, empirical studies have revealed that compared with Asian parents, European American parents are often more eager to engage their children in conversations about the past and focus more on the children's own feeling states during the conversations (Fivush & Wang, 2005; Martini, 1996; Minami & McCabe, 1995; Mullen & Yi, 1995; Wang, 2001b). During a 1-day observation of European American and Korean mother-child conversations, Mullen and Yi (1995) found that American mothers talked with their 3-year-olds about past events three times as often as Korean mothers did. Martini (1996) observed that during evening meals at home, European American parents were twice as likely as Japanese American parents to ask their children to talk about past events.

In a related series of studies, researchers have examined mother-child conversations about emotional events (Fivush & Wang, 2005; Wang, 2001b; Wang & Fivush, 2005). When European American and Chinese mothers were asked to nominate positive events to discuss with their children, they chose similar types of occurrences. In both groups, the majority of events (U.S. parents, 81%, Chinese parents, 83%) concerned family activities, parties, vacations, and holiday events (Wang & Fivush, 2005). The memory conversations were similar in length, and mothers in both cultures spoke more than their children. Nevertheless, compared with Chinese mothers and children, European American mothers and children engaged in more interactive conversations about

these happy episodes, whereby mother and child frequently took turns in participating in the conversation (Wang, 2001b; Wang & Fivush, 2005).

When discussing negative emotional experiences, European American mother-child dyads were also more interactive than were Chinese dyads. Furthermore, the negative events most frequently selected by American mothers concerned child injuries/illnesses (26%), and frightening events and objects such as thunderstorms and monsters (26%). After the conversation, American mothers often reassured their children that everything was all right (e.g., "It's really nothing to be scared about in the pool. Daddy was there, and you've got a big floater"). A focus on the child's emotions and the mother's corresponding sympathetic responses conceivably helps to reinforce the intimacy of a conversational exchange. Chinese mothers, however, most frequently selected social conflicts between their children and significant others, such as parents and peers (58%). The significant other was frequently a third party that was not present during the memory conversation. Chinese mothers often tried to restore the harmonious relationship between the child and the individual who caused the negative emotion in the child (e.g., "Dad didn't let you play with that bottle because it's dangerous to little children. He loves you"). They also taught children "moral lessons" about the inappropriateness of their negative emotional experience or behavior (e.g., "Isn't it wrong for you to get mad at Papa?"). Chinese mothers seem to use memory conversations to resolve conflicts between the child and significant others, and to establish the child's proper place in his or her social world (Wang, 2004b).

Emotional Regulation

In Western cultures, most scientific researchers and advice columnists emphasize the harmful effects of bottling up emotions, as well as the benefits of discussing stressful experiences with others, including therapists (for reviews, see Pennebaker, Zech, & Rimé, 2001; Rimé, Corsini, & Herbette, 2002; see van Emmerik, Kamphuis, Hulsbosch, & Emmelkamp, 2002, for a dissenting opinion). In traditional Chinese medicine there are indications of Western-like talk therapies. However, Chinese patients often expect an "authoritative" physician to detect their emotional problems from nonverbal cues

and are reluctant to provide elaborate accounts. Professional psychotherapy and counseling services appear to be more recent trends in China (Cheung, 1986).

The use of memory talk for therapeutic emotional regulation is further shaped by different cultural beliefs concerning emotion and emotion sharing, which are often mirrored in divergent socialization goals and practices. Studies with Western families indicate that early family emotional discourse, including references to feeling states and causal explanations, helps children to understand and to regulate their emotions (Bretherton, Fritz, Zahn-Waxler, & Ridgeway, 1986; Denham & Kochanoff, 2002; Denham, Zoller, & Couchoud, 1994; Dunn, Brown, & Beardsall, 1991; Fivush, Berlin, Sales, Mennuti-Washburn, & Cassidy, 2003). In memory conversations about positive or negative emotional experiences with their 3-year-old children, European American mothers often employed a "cognitive approach" to emotional regulation (Wang, 2001b; Wang & Fivush, 2005). The mothers frequently talked with their children about the causes and consequences of feeling states and provided elaborate explanations as to why and how an emotion was experienced. Such emotional discourse highlights the personal importance of emotion and facilitates the development of children's emotional understanding and regulation. The following conversational excerpt of an American mother and her 3-year-old daughter is illustrative (Wang & Fivush, 2005):

MOTHER: . . . Do you remember doing some crying?

CHILD: Why did I cry?

MOTHER: I'm not quite sure why you cried. But do you remember where you were?

CHILD: I cried because I had any, no any balloon.

MOTHER: They had no balloons. But then, were you also crying because, did you not want to go home?

CHILD: Yeah.

MOTHER: Where were you?

CHILD: At Stewart Park!

MOTHER: (*Laughs.*) You did cry a lot at Stewart Park, but, um, this was in Joe's parking lot. Do you remember Joe's Restaurant parking lot? Do you remember standing by the door and crying?

CHILD: Yeah.

MOTHER: You do?

CHILD: Yeah.

MOTHER: What were you crying about?

CHILD: 'Cause I didn't wanted to leave yet; it was because I wanted to eat.

MOTHER: Oh, you wanted to eat some more (*laughs*). Is that why?

CHILD: Yeah.

MOTHER: Hmm. I remember Mommy tried to pick you up and you put up a little bit of a fight. You were crying real hard. Maybe it was 'cause of the balloon and maybe it was 'cause you were hungry. But we knew that you could get another balloon, right?

CHILD: Yep.

In contrast, Chinese mothers tended to use a “behavioral approach” to emotional regulation that focused on proper behavior and provided few causal explanations for the emotion itself. Although mothers attributed emotions to the child and other people involved in the memory event, they rarely went further to discuss the causes and consequences of the emotions. Emotion, particularly negative affect, was often depicted as a result of the child's past wrongdoing. Mothers led their children to the understanding that they should behave properly in the future to avoid negative emotion. The following conversational excerpt between a Chinese mother and her 3-year-old son is illustrative (Wang & Fivush, 2005):

MOTHER: Do you remember why Dad spanked you last time?

CHILD: Chess!

MOTHER: Why chess? What did you do with chess?

CHILD: Not obedient!

MOTHER: How were you not being obedient?

CHILD: I threw the pieces on the floor.

MOTHER: All over the floor, right? And did you do it on purpose?

CHILD: Umm. I'll be careful next time!

MOTHER: Right! That's why Dad spanked your bottom, right? . . . Did you cry then?

CHILD: I cried.

MOTHER: Did it hurt?

CHILD: It hurt.

MOTHER: It hurt? It doesn't hurt anymore, right?

CHILD: Right. I'll be careful next time.

MOTHER: Umm, be careful.

Studies of adults have suggested cultural variation with regard to how, when, with whom, and to what extent emotions are shared in memory conversations (Rimé et al., 2001, 2002). Koreans reported that 20% of their emotional experiences were never shared; for U.S. participants, the comparable figure was only 5%. French and U.S. respondents also claimed to have repetitively shared a single emotional episode with others more frequently (about five times) than did Korean, Singapore, and Japanese respondents (two or three times). In addition, Westerners reported sharing the emotional event sooner after its occurrence (a delay of 1 or 2 days) than did Asians (4–5 days in the case of Singaporeans). Although people in both Western and Asian cultures reported sharing emotions most frequently with best friends and rarely with strangers, French and U.S. participants were more inclined to share emotions with their family members (spouse, parents, siblings, and grandparents) than were Asians (see Rimé et al., 2002). These findings should be treated with caution, because they depend on the accuracy of people's retrospective reports of frequency and dates, which can be quite unreliable (e.g., Tanur, 1992). Nonetheless, the findings again suggest varied cultural views of the social sharing of emotional experiences and the functions such memory conversations may serve.

Memory Conversations and the Development of Autobiographical Memory

Early parent–child memory sharing appears to be critical to the emergence and development of autobiographical memory (Nelson & Fivush, 2004). Parents play a guiding role as they discuss shared experiences and encourage their children's active participation in the conversations. These exchanges show children how to represent memory information verbally and provide them with a framework for organizing and structuring their personal memories (Harley & Reese, 1999; Leichtman, Pillemer, Wang, Koreishi, & Han, 2000; McCabe & Peterson, 1991; Fivush, 1994). By modeling par-

ents' conversational styles and ways of thinking and talking about the past, children further learn to evaluate, remember, and share past experiences in a culturally acceptable fashion (e.g., Minami & McCabe, 1995; Wang & Brockmeier, 2002). Culture-specific ways of memory sharing may thus have important consequences for children's developing autobiographical memory.

Memory conversations differ across cultures in content and in the degree of elaboration and support that mothers provide to their young children (S. H. Choi, 1992; Martini, 1996; Minami & McCabe, 1995; Mullen & Yi, 1995; Wang, 2001b; Wang & Fivush, 2005; Wang, Leichtman, & Davies, 2000). Western mothers often engage their children in elaborate memory conversations, in which they provide detailed information and feedback to maintain children's active participation. Moreover, Western mothers frequently focus discussions on their children's roles and predilections, asking them what they want, what they think, and how they feel. Such conversations provide a model of autobiographical memory that highlights the child's role as an autonomous being with distinctive and unique characteristics. Asian mothers, in contrast, often play a directive role when sharing memories with their children. They tend to initiate test-like conversations, provide less elaboration or help to engage the child, and place past events in a relational context by focusing on group actions. Consistent with a cultural emphasis on the moral value of the past, Asian parents often include teaching and moralizing in their conversations with their children (Miller et al., 1996, 1997; Mullen & Yi, 1995; Wang, 2001b, 2004b; Wang et al., 2000). Such conversations direct children to pay attention to the roles of significant others and to monitor their own behavioral conduct when remembering past experiences.

The stylistic and content differences in early parent-child reminiscing are mirrored in children's independent memory reports (Han et al., 1998; Wang, 2004a; Wang & Leichtman, 2000). When recounting their personal experiences with a researcher, European American preschool and grade school children often provide elaborate and detailed memory narratives, and frequently comment on their own feelings, preferences, and opinions. In comparison, Asian children often provide "bare-bones" accounts of the past, speak frequently of significant others and social interactions, and show a concern for moral correctness and authority.

Although Asian parents generally provide less support than Western parents to encourage their children to give detailed recollections during memory conversations, some mothers in both cultures are more elaborative than others. For instance, within a culture, mothers differ in the degree to which they use elaborative questions during memory conversations with their young children (e.g., "Do you remember what we did at the party?"). Differences in maternal reminiscing style appear to have both immediate and long-term influences on children's remembering. Western children whose mothers are highly elaborative provide more detailed memories to their mothers during the memory conversations. Moreover, these same children independently provide more detailed personal memories weeks and even years later (e.g., Harley & Reese, 1999; McCabe & Peterson, 1991). In a recent longitudinal study with native Chinese families in China, immigrant Chinese families in the United States, and European American families, Wang (2005, in press) found the same pattern of results. Maternal reminiscing styles had immediate and long-term effects on children's shared and independent recall. More important from the current perspective, mothers' use of elaborations was positively associated with their value orientation toward independence and an autonomous self-construal.

This research suggests that early parent-child memory conversations lead children to remember and talk about their personal experiences in culturally acceptable ways. As Pillemer (1998) noted, "Parents' implicit or explicit communicative goals influence which functions will assume center stage in the child's own memory operations" (p. 129).

LANGUAGE AND MEMORY

If parent-child memory conversations are critical to the development of autobiographical memory, then it would seem that language is also important to the development of autobiographical memory. However, language is not essential for remembering. Dogs recognize people and remember how to respond to verbal and physical commands. Young infants remember faces, voices, pictures, and actions long before they acquire language (Bauer, 2002). Although language is not essential for memory, it probably is necessary for autobiographical memory (Nelson & Fivush, 2004). It is unlikely

that dogs or young infants possess autobiographical memory, which would include details such as where, when, and why they acquired their knowledge.

Language plays a role in a young child's developing memory skills by providing both a communicative and a representational tool for remembering (Nelson & Fivush, 2004). Through narrative practices and language socialization in general (e.g., Ochs, 1996), language serves as an important vehicle for cultural messages about what to remember, how to remember, and why to remember it. Some theorists argue that the social-cognitive shift associated with the acquisition of language helps to explain people's inability to remember events from their first years of life (Neisser, 1962; Schachtel, 1947). Schachtel attributed early memory loss to the shift from preverbal to language-based cognitive schemas. According to Schachtel, this shift produces new modes of social-cognitive activity that cannot be fully integrated with earlier representations; as a result, very few early memories are preserved. A study by Simcock and Hayne (2002) provides support for Schachtel's proposal that children cannot translate prelinguistic experience into language. Young children participated in a unique event, and their memories were assessed 6 months or 1 year later. Children demonstrated both verbal and nonverbal memory of the event. Yet children *never* recalled any information about the event in words if they could not talk about that information when the event first occurred, even though they had acquired the language skills to do so by the time of recall.

Researchers have also studied the effects of acquiring a second language on recall. Cultural practices and meanings are so deeply embedded in language that the acquisition of a second language often entails the establishment of a new cognitive system—schemas, mental models or representations—that reflects new ways of construing the social and physical world (Kim, 2002; Ochs, 1996; Schrauf, 2000; Valsiner, 2001). As a result, bilingual individuals may possess separate knowledge structures that are activated by the associated language. Ross and colleagues (2002) surveyed Chinese-born bilingual students living in Canada. The survey was conducted in either Chinese or English. Those who participated in Chinese described themselves in more collective terms and endorsed traditional Chinese values more strongly than did those surveyed in English. In-

deed, the responses of the bilingual group interviewed in English were barely distinguishable from the responses of European Canadians.

In a related experiment, Hoffman, Lau, and Johnson (1986) had Chinese-English bilinguals read character descriptions written in either English or Chinese and respond to questions using the language of the descriptions. Some of the descriptions reflected a personality type, with an economical label or schema available in English but not in Chinese (liberal type, artistic type). Some of the descriptions reflected a personality type with an economical label available in Chinese but not in English. For example the Chinese term *shi-gu* applies to a person who has traveled a lot, has varied job experiences, is devoted to his family, and has good interpersonal skills. Although each of these attributes is familiar to English speakers, there is no English personality term or schema that readily captures the complete set of attributes. After reading the passages, participants were tested for their ability to recognize statements from the descriptions. Those participating in Chinese showed better recognition for statements from descriptions that had economical Chinese labels. Those writing in English showed better recognition for statements from descriptions that had economical English labels. In short, memory was better if participants could link the material to preexisting, language-specific cognitive schemas.

The association between cognitive frameworks and language further implies that people should remember events better in the language in which they originally encoded them. Marian and Neisser (2000) tested this hypothesis on Russian-English bilinguals and found language-dependent recall. Participants retrieved more memories from the Russian-speaking period of their lives when interviewed in Russian, and more memories from the English-speaking period of their lives when interviewed in English. In addition, memories recalled in English tended to be more self-focused, whereas memories recalled in Russian were more other-oriented (Marian & Kaushanskaya, 2004), suggesting that language at retrieval can bring memory in line with cultural value systems. Schrauf and his colleagues have also shown that bilingual immigrants can recall childhood events (occurring in the country of origin) better in their mother tongue than in their adopted language (Larsen, Schrauf, Fromholt, & Rubin, 2002; Schrauf, 2000; Schrauf & Rubin, 2000). Moreover, peo-

ple's internal language of retrieval is consistent with the language at encoding. For instance, Hispanic bilingual immigrants in the United States report retrieving autobiographical memories in Spanish for events occurring in their country of origin, and in English for events occurring in the United States (Schrauf & Rubin, 2000). These findings suggest that memory information is specific to the semantic and lexical systems of the language at encoding and is more accessible when congruent systems are activated at retrieval (Marian & Neisser, 2000; Schrauf, 2000).

AGING, MEMORY, AND CULTURE

In contrast to the rather extensive cross-cultural literature on children's memory, there is relatively little cross-cultural research being conducted at the opposite end of the age spectrum. Psychological research on Western participants reveals age-related declines in memory (Craik, 2000). Is the memory decline in later adulthood a cultural artifact due to negative stereotypes about aging? Levy and Langer (1994) reported a study that seemed to support this view. They hypothesized that in cultures such as China, where attitudes toward the elderly are more favorable than in the West, age-related declines in memory should be less apparent. Levy and Langer provided nonverbal memory tests to younger and older mainland Chinese and to Americans. Older Chinese performed better than their American counterparts, and not significantly worse than younger Chinese. As is typically the case on these types of memory tests, younger Americans outperformed older Americans.

Yoon, Hasher, Feinberg, and Rahhal (2000) noted several problems with the Levy and Langer (1994) study, ranging from low sample sizes to the possibility that the memory test might have been biased in favor of the Chinese. Yoon and colleagues (2000) studied older and younger Chinese Canadians who had lived in Canada for less than 5 years, as well as older and younger Anglophone Canadians. Their main finding was that, regardless of culture, younger adults outperformed older adults on a variety of memory tests. On two memory tests that might be biased in favor of Chinese participants (as a result of differing cognitive processing abilities engaged by written Chinese and English), older Chinese outperformed the

older Anglophone Canadians, but still did not perform as well as their younger Chinese counterparts. At this point in time, there does not seem to be strong evidence of cultural differences in age-related memory decline.

LOOKING AHEAD

We have shown that culture contributes to how, when, what people remember, and whether they judge remembering to be important at all. We have also shown that cultural influences take place in the larger context of setting the goals and purposes of remembering, in the interpersonal sphere of daily mnemonic practices and exchanges, and at the individual level of shaping cognitive schemas and memory strategies. As both a system and a process of symbolic mediation, culture manifests itself in memory construction via multiple pathways (e.g., Cohen & Gunz, 2002; Kearins, 1981; Ross et al., 2005; Wang, Hutt, Kulkofsky, McDermott, & Wei, 2006).

In recent decades, Western countries have opened their borders to increasing numbers of immigrants from Asian cultures, and psychologists are now shifting their focus from international comparisons of cognition and behavior to an examination of Asian immigrants. Many of these immigrants lead a bicultural life, switching cultural frames and identities across situations and languages (Benet-Martinez, Leu, Lee, & Morris, 2002; Perunovic, Ross, & Wilson, 2005). In this multicultural context, experimental and longitudinal studies of development will be needed to reveal how cultural influences are transmitted to and internalized by individuals, and further manifested in their memory operations. Future research should also go beyond the East–West dichotomy and examine other cultures, as well as heterogeneity within a culture, such as differences in demographic patterns, economic progress, and educational facilities.

Finally, a historical perspective will further our understanding of the influence of culture and cultural transformation on the workings and functions of memory. The changing nature of autobiography illustrates the potential value of historical analyses. Since its emergence, autobiography has been undergoing continuous changes in accordance with the cultural and technological changes in contemporary societies. In recent years, the tendency toward public

self-revelation and autobiographical accounting has perhaps reached new heights in the form of blogs posted for all interested viewers on the Internet. The postings are selective and idiosyncratic, but then so are most autobiographies. Researchers interested in autobiographical memory will no doubt avail themselves of this rich Internet resource that has the potential to transcend many linguistic and cultural boundaries.

At the outset, we noted that the subject of memory in general, and autobiographical memory in particular, has received increasing attention in recent years. The extensive theories and empirical findings we have discussed in this chapter further elucidate an exciting field of scientific inquiry. Still greater efforts are required from memory researchers in different fields of psychology, in collaboration with those in anthropology, sociology, education, ethnography, linguistics, philosophy, and literature, to take a multidisciplinary approach and draw on diverse theoretical perspectives to address the central role of culture in remembering. Only then can we reach a genuine understanding of human difference, experience, and complexity in the processes and functions of memory.

CHAPTER 27

Language, Cognition, and Culture

Beyond the Whorfian Hypothesis

CHI-YUE CHIU
ANGELA K-Y. LEUNG
LETTY KWAN

The idea that every distinctive language would give rise to a distinctive culture stayed at the center of American anthropology throughout much of the 20th century. According to Benjamin Whorf (1956), who had written most enthusiastically on the linguistic shaping of thoughts and culture, “Users of markedly different languages are pointed by their grammars toward different types of observations, and hence are not equivalent as observers but must arrive at somewhat different views of the world” (p. 252). In other words, the grammar of a language constrains the way its speakers perceive the world and mentally represent what they perceive. As a result, there is an isomorphic relation between the structure of a language and the mental processes of the people who speak it. This idea is often referred to as *linguistic relativity*.

Whorf also held that in the coevolution of language and culture, “the nature of the language is the factor that limits free plasticity and rigidifies channels of development [of culture] in the more autocratic way” (Whorf, 1956, p. 156). Thus, the grammar of a language is

taken to be the cause of the speakers’ cognitions. This assumption is often referred to as *linguistic determinism* (Chiu, Krauss, & Lee, 1999).

The original form of linguistic determinism consists of six propositions:

1. There is no inherent structure in people’s experiences; perceptual order emerges when people organize their experiences with mental categories.
2. Language is a major cognitive tool people use to categorize their experiences.
3. As a language evolves, it develops a coherent internal logic.
4. The internal logic of a language embodies a metaphysics or naive conception of the reality; as such, the internal logic of a language stands in isomorphic relation to that of its associated culture.
5. Markedly different languages evoke in the mind of its speakers different mental representations of similar linguistic referents.
6. Language constrains the development of nonlinguistic cultural norms.

Taken together, these propositions imply that the structural properties of a language have general effects on cognition that extend beyond the immediate context of language use.

Whorf's writings have inspired a search for the linguistic foundation of human sociality in social psychology. However, the original form of linguistic determinism, inspiring as it is, lacks the empirical support needed to sustain the early enthusiasm for it (Brown, 1976; Glucksberg, 1988). The demise of the Whorfian hypothesis has led to a decline in interest in the linguistic foundation of culture in social psychology, and to an overriding concern with language universals in linguistics. As Chomsky (1992) puts it, "The computational system of language that determines the forms and relations of linguistic expressions may indeed be invariant; in this sense, there is only one human language, as a rational Martian observing humans would have assumed" (p. 50).

Language is a polysemous word, with both a generic sense (as in "Language pervades our social life") and a specific sense (as in "English is a language spoken by most Americans"). These two senses are related but not synonymous. Whorf (1956) clearly intended the specific sense of *language*, and the empirical support for Whorf's formulation of linguistic determinism is tenuous (Glucksberg, 1988). Despite this, there is considerable evidence that language (in its generic sense) can, under some circumstances, affect the way we think, remember, and perceive. Advances in the cognitive and linguistic sciences have provided much new knowledge about the mechanisms of cognition and their relations to various aspects of language. These developments lead to alternative views of how language may be implicated in cognitive processes such as memory, categorization, thinking, and problem solving (e.g., see Hoosain, 1991; Hunt & Agnoli, 1991). They also suggest some of the conditions and mechanisms for such cognitive effects of language (Hunt & Banaji, 1988).

In this chapter, instead of questioning whether we should accept or reject the Whorfian hypothesis, we focus on how language may be implicated in human cognitions. We posit that the availability of certain structural properties in a language is *important but not sufficient* for it to affect cognitions. Instead, we suggest that the vocabulary of a language provides its speakers with some *linguistic tools* for encoding experiences and

expressing thoughts, and that these tools may influence cognitions *only when they are used*. Furthermore, when used in a communication context, because of the interactive nature of communication, aside from being a tool for expressing thoughts and ideas, language is also a tool for negotiating shared meanings in the context.

As an illustration of these arguments, consider a hypothetical scenario in which a person with no knowledge of Chinese characters is asked to describe Figure 27.1a. The description is likely to be rather lengthy, with plenty of details of the figure's components (e.g., the flattened oval on the top, the cross below it, the curved arms that extend to both sides, and the tail pointing to the left). In contrast, a person who has good command of the Chinese language may refer to this figure simply as "the ancient form of the character *zi*" (child; see Figure 27.1b for the modern form the character). This example illustrates how the availability of a linguistic code (*zi*) in a language (Chinese) for encoding a stimulus affords an economical referring expression of the stimulus.

When language is used to characterize a state of affairs, a linguistic representation of that state of affairs is created or evoked. For example, an English speaker may use the color term *blue* to describe a greenish-blue chromatic light that has the wavelength of 490 μm . As a result, the light is linguistically represented as "a blue light." Linguistic representations may then compete with and overshadow the perceptual representations of that state of affairs. In the previous example, the linguistic representation (*blue light*) may compete with and overshadow the original visual representation of the light (a greenish-blue light of 490 μm). Consequently, the speaker may visualize and remember the

FIGURE 27.1. Ancient (a) and modern (b) forms of the Chinese character *zi* (child).

light as being bluer than it is (Thomas & DeCapito, 1966).

Members of a speech community share not only the formal rules of a language but also the ground rules and assumptions that underlie language usage. According to Grice (1975), communication is a collaborative activity. In a conversation, the speakers are expected to make their contribution “as informative as is required, at the stage at which it occurs, by the accepted purpose or direction of the talk exchange” (p. 45). The speaker is expected to be aware of these rules and adhere to them. Back to the example of describing the old form of the Chinese character *zi*, when the Chinese speaker describes it to someone who knows nothing about Chinese characters, it is unlikely that she would refer to it simply as “the old form of the Chinese character *zi*,” because she expects her addressee not to possess the knowledge necessary to identify the referent from this expression. Instead, she may say something like “This is the old form of the Chinese character *zi*; it has a flattened oval on the top and a cross below it” (Lau, Chiu, & Hong, 2001).

A grounding process is implicated in interpersonal communication. At the beginning of the conversation, the speaker’s utterance represents his or her hypothesis about what the addressee will understand, and the addressee has a hypothesis about what the speaker means by the utterance (Clark & Brennan, 1991). Furthermore, as the conversation proceeds, the participants use each other’s response as evidence to test and revise their hypotheses. They acquire common ground and eventually establish consensus on the referential meanings of the stimulus. An indication of this grounding process is that the referring expression would become much shorter and more efficient after the speaker has described the same referent to the same speaker several times (Krauss & Glucksberg, 1977). In this example, the referring expression of Figure 27.1a becomes shorter (“the old form of *zi*”) after the Chinese speaker has described it to the same addressee several times. Eventually, both participants agree to refer to it as “the old form of *zi*.” In short, language is not merely a tool for expressing thoughts and ideas; it is also a tool for negotiating meanings: Through the use of language in communication, private cognitions are rendered public and directed toward a shared representation of the referent (Schegloff, 1991).

In summary, like Whorf, we hold that language has important influences on human cognitions. However, unlike Whorf, we submit that the structural properties of a language do not rigidly determine thoughts. Instead, grammar and vocabulary limit the tools that are available to speakers of the language for constructing and negotiating meanings. The emergent properties of the communication context constrain the likelihood and the manner that certain expressions or ways of expressions in a language will be evoked and applied in the context. These processes may in turn direct the development of shared cognitions in the speech community. In the sections that follow, we review the evidence for these ideas.

LANGUAGE AND MIND: THE EMPIRICAL EVIDENCE

To recap, we posit that (1) the availability of certain structural properties in a language is *important but not enough* for language to impact cognitions; (2) the characteristic ways of referring to a state of affairs in a language are *linguistic tools* speakers of the language can use to encode experiences and express thoughts; (3) these tools influence cognitions only when they are used; (4) when language is used to characterize a state of affairs, a linguistic representation of that state of affairs is created or evoked, which may compete with and overshadow the perceptual representation of that state of affairs; and (5) individuals who participate in communication acquire common ground and eventually establish consensus on the referential meanings of the stimulus through communication. In this section, we review the empirical evidence for these five propositions.

Grammar and Thought

The original form of the Whorfian hypothesis focuses on the relationship between a language’s grammar and the language users’ cognitions. According to Whorf (1956), “It is not words mumbled, but *rapport* between words, which enables them to work together at all to any semantic result” (p. 67; emphasis in original). “Words and speech are not the same thing. . . . The patterns of sentence structure that guide words are more important than the words” (p. 253). In his view, an integrated “fashion of speaking” shapes the linguistic as-

pects of thoughts. Whorf used the term *cryptotype* to refer to “a submerged, subtle, and elusive meaning, corresponding to no actual word, yet shown by linguistic analysis to be functionally important in the grammar” (p. 70). An example of cryptotype is the inanimate object class in Navaho (a Native American language). Navaho classifies inanimate objects into “round objects” and “long objects,” and a different verb stem is required for a “round” or a “long” subject (or object) in a sentence. Whorf believed that an analysis of *cryptotypes* is needed to reveal the linguistic aspects of thinking.

Research inspired by Whorf’s ideas has provided some support for the idea that the grammar of a language encodes a cultural worldview (the linguistic relativity hypothesis). However, the idea that the cognitive effects of a language’s grammar extend beyond the immediate context of language use (the linguistic determinism hypothesis) has received little support.

Grammar Encodes a Cultural Worldview

Whorf and his followers assumed that the grammatical structure of every language embodies a cultural worldview. There is some evidence for this assumption. For example, the system of pronouns in a language reflects the conceptions of the social self in the culture. The use of a pronoun sustains attention on its referent, bringing the person out from the conversational background. In some languages (e.g., English), the use of a pronoun is grammatically obligatory. In other languages (e.g., Spanish), the subject pronoun can be dropped, because the referent can be recovered from the verb inflections. In some languages (e.g., Chinese), the subject pronoun can be dropped even though there is no verb inflection, or the subject–verb agreement rule. The grammatical obligatory use of the first-person pronoun maximally distinguishes the speaker’s self. Similarly, obligatory use of the second-person pronoun maximally distinguishes the addressee(s). The omission of either or both of the two classes of pronouns deemphasizes the salience of their corresponding referent(s).

Consistent with the idea that language encodes cultural conceptions of the self, groups whose language allows pronoun drop tend to stress the importance of being interdependent with the social world, maintaining good rela-

tionship and fitting in, whereas groups whose language disallows pronoun drop tend to stress the desirability of being independent from people around them and expression of the inner set of attributes and abilities (E. Kashima & Kashima, 1998; Y. Kashima & Kashima, 2003).

How individuals process verbal and coverbal information may also reflect their cultural worldview. Listeners tend to extract different information from an utterance’s verbal contents and coverbal cues (e.g., vocal tone, gesture, gaze pattern); they extract the utterance’s intended meanings from its verbal contents, and infer contextual information (e.g., the speaker’s status, personality characteristics, and emotional states) from coverbal cues (Krauss & Chiu, 1988). Consistent with the view that American societies are low-context societies, in which people tend to have many connections but of shorter duration, or for some specific reason, knowledge is codified, public, external, and accessible, and cultural beliefs and expectations are spelled out explicitly, and Japanese societies are high-context societies, in which people have long-term relationships, knowledge is situational and relational, and verbally explicit communications are infrequent (see Hall, 1990), European Americans respond automatically to the verbal contents of a message, and Japanese respond automatically to the vocal tone (Ishii, Reyes, & Kitayama, 2003). In short, a language’s grammar and the way language is processed may reflect the implicit organization of knowledge in the language community.

Linguistic Determinism: A Strong Claim in Search of Evidence

In the original formulation of the Whorfian hypothesis, the *structural aspects* of a language are assumed to *shape* the way its speakers *habitually* represent the reality. For example, time is a continuum. However, in standard average European (SAE) languages, no formal markers distinguish real plurals (e.g., seven dogs) from imaginary plurals (e.g., seven days). According to Whorf, because of this linguistic property, speakers of SAE languages may habitually assume that time can be dissected into discrete units (e.g., days, weeks). Whorf also believed that the three-tense (past, present, and future) system in SAE verbs predisposes speakers of SAE languages to the perception of time as a

straight line extending from the past to the present, and the future. In short, in Whorf's view, speakers of languages with markedly different grammars are linguistically predisposed to different perceptions and representations of otherwise identical experience (e.g., time).

As noted, there is consistent evidence that the grammar of a language may embody a certain cultural worldview. However, support for the idea that the cognitive effects of a language's grammar extend beyond the immediate context of language use is tenuous. Research that directly tested the linguistic determinism hypothesis has examined the cognitive effects of grammatical markers of shapes, counterfactual ideas and entification, gender, and false beliefs. As described below, no conclusive evidence for linguistic determinism was found in this research.

GRAMMATICAL MARKERS OF SHAPES

In an early study, Carroll and Casagrande (1958) presented to Navaho-speaking children, English-speaking Navaho children, and white middle class children in Boston two objects that differed in color and shape. Next, they showed a third object similar to the first two objects either in color or in shape, and had the participants indicate which of the first two objects went best with the third one. The results are equivocal. Consistent with the linguistic determinism hypothesis, when compared to the English-speaking Navaho children, Navaho-speaking children were more inclined to group objects with a similar shape together. However, contrary to the linguistic determinism hypothesis, when compared to the English-speaking Boston children, Navaho-speaking children made *fewer* shape-based choices.

COUNTERFACTUAL REASONING AND ENTIFICATION

Unlike English, Chinese lacks formal grammatical markers for counterfactuals. Also, unlike English, Chinese does not have a formal way to express a condition or event as an entity (entification). Bloom (1981a) posits that these two grammatical features hinder Chinese speakers' development of conceptual schemas for abstract, theoretical thinking. He further argues that the Chinese way of speaking shapes Chinese speakers' moral outlook, orienting them toward pragmatic moral beliefs, and

away from a formalized theoretical approach to morality (Bloom, 1981b).

Findings from several studies seemed to support Bloom's views. In one study, Chinese speakers and English speakers read a passage that contained counterfactual statements in their respective native languages. Later in the study, their comprehension of the passage was tested. English speakers did much better than Chinese speakers on the test. Moreover, Chinese-English bilinguals performed much better on the English version of the test than on the Chinese translation of it (Bloom, 1981a). Bloom believes that the lack of formal markers for counterfactuals in the Chinese language hinders its speakers' counterfactual reasoning ability.

However, Bloom's findings are difficult to interpret, because the English passages in his studies were written in idiomatic English, but the Chinese passages were not written in idiomatic Chinese (Au, 1983, 1984, 2004). Thus, the two versions of the passages are not equally comprehensible. Indeed, when the Chinese version was rewritten in idiomatic Chinese, Chinese and English speakers performed equally well on the comprehension test. Moreover, when English speakers were presented with English passages written in nonidiomatic English, they made a considerable amount of comprehension errors (Au, 1983). Furthermore, Chinese grade-school children who have almost no knowledge of English subjunctive understand counterfactual statements (Au, 1983; Liu, 1985). Finally, among Chinese-speaking children with little exposure to the English language, the ability to understand counterfactual statements increases with age. By age 11, almost all Chinese children who know little English can solve counterfactual problems (Liu, 1985). In short, it seems that counterfactual reasoning ability increases with cognitive maturity and is not related to the language one speaks.

Does the lack of formal entification markers in the Chinese language hinder its speakers' formal reasoning ability? To answer this question, Bloom (1981a) developed another comprehension test. The test passage contained factual information about the relationships of different events. To answer the comprehension question correctly, these events need to be transformed into entities and placed into a theoretical framework. As Bloom expected, Chi-

nese speakers performed more poorly on this test than did English speakers.

However, to Bloom's embarrassment, Takano (1989) pointed out that the designated correct answer in Bloom's comprehension test was actually an incorrect answer. Moreover, among the undergraduates who had taken Bloom's test, those with more formal training in scientific reasoning were *less* likely to choose the designated correct answer. Furthermore, those who challenged the validity of Bloom's comprehension question were able to provide better explanations of the functional relationships among the variables described in the passage than those who chose the "correct" answer.

GRAMMATICAL GENDER

Grammatical gender research provides another opportunity to test the effects of grammar on cognitive representations. Languages differ in whether they assign a gender to all nouns that refer to animates (e.g., *psychologist*) or to nouns that refer to inanimates (e.g., *moon*). Some languages (e.g., Spanish, Italian, French, German, Arabic, and Hebrew) mark gender with morphological information carried by pronouns, determiners, nouns, and adjectives, and others (e.g., English) do not. It is often assumed that, at least in most European languages, the basis of grammatical gender assignments to inanimate objects is arbitrary. For example, in French, the word for "the moon" is feminine (*la lune*) and the word for "the sun" is masculine (*le soleil*). However, in German, "the moon" is masculine (*der Mond*) and "the sun" is feminine (*die Sonne*).

Some studies suggest that users of a language with a grammatical gender system tend to infer psychological gender properties from gender inflections of nouns. For example, French speakers conceptualize the moon in more psychologically feminine ways and the sun in more psychologically masculine ways than do German speakers. In a classic study, Ervin (1962) taught native speakers of Italian nonsense words that possessed either the masculine Italian affix (-o) or the feminine one (-a). In this study, the participants rated the nonsense words with masculine endings as more like men than those with feminine endings, and vice versa. Similar results have been obtained in speakers of Arabic (Clarke, Losoff,

McCracken, & Rood, 1984; Clarke, Losoff, McCracken, & Still, 1981). However, because participants in these studies were asked to judge the gender connotations of words, it is unclear whether these judgments reveal participants' knowledge of grammatical gender or the effects of grammatical gender on categorization (see Sera et al., 2002). Nonetheless, other studies have used more sophisticated tests of categorization to assess the effects of grammatical gender. For example, participants were shown pictures (vs. words) of objects and asked to assign either a man's voice or a woman's voice to the objects. Using these methods, researchers have obtained robust effects of grammatical gender on object categorization in Spanish (Martinez & Shatz, 1996; Sera, Berge, & del Castillio Pintado, 1994; Sera et al., 2002) and French speakers (Sera et al., 2002). These findings seem to support the linguistic determinism hypothesis.

However, two problems undermine the validity of this conclusion. First, the effects of grammatical gender on object categorization are not uniform across languages with a grammatical gender system. For example, the cognitive effects of grammatical gender are absent in Finnish speakers (Clarke et al., 1981, 1984) and German speakers (Sera et al., 2002). Second, although assignments of gender to objects are mostly arbitrary in some languages (e.g., German), this is not the case in other languages (e.g., Spanish). For example, in Spanish, a female gender is often attributed to an object that is used by women, natural, round, or light. Likewise, a male gender is often attributed to an object that is used by men, artificial, angular, or heavy. Moreover, native speakers of English (a language without a grammatical gender system) tend to assign male or female voices to pictured objects corresponding to Spanish gender. Thus, Spanish grammatical gender seems to be highly correlated with natural gender. In a series of computer and experimental simulation studies, Sera et al. (2002) found that generalization of masculine and feminine traits to inanimate objects is likely to occur when the grammatical gender system has only two gender categories, and when there is a high correlation between grammatical and natural gender. The result of this simulation study is consistent with the empirical observation that grammatical gender effect is found among Spanish speakers but not among German

speakers. In short, the weight of the evidence to date is in favor of the conclusion that object categorization by gender may stem from the natural gender associations of objects. Natural and grammatical gender may or may not correspond. Grammatical gender effects are likely to be found only when they do.

FALSE BELIEFS

Puerto Rican (PR) Spanish and Turkish have formal verb forms for marking false belief states explicitly. For example, PR Spanish uses *creer* to denote that the speaker is neutral on whether the grammatical subject in the sentence holds a true belief or not, and adds a reflexive clitic to the verb phrase (*creer-se*) to denote that the speaker is sure that the grammatical subject holds a false belief. English and Brazilian (BR) Portuguese have no such specific forms. Shatz, Diesendruck, Martinez-Beck, and Akar (2003) compared the performance on a false belief understanding task of PR Spanish-speaking preschoolers and Turkish-speaking preschoolers with their English-speaking and BR Portuguese-speaking counterparts. In this study, Experimenter 1 showed the preschooler in the presence of Experimenter 2 a crayon box and a blue box. Then, after Experimenter 2 left the room to get some paper, Experimenter 1 opened both boxes, remarked that the crayon box was empty and the blue box contained crayons, and asked the preschooler, "Where does [Experimenter 2] think the crayons are?" and "Where is [Experimenter 2] going to look for the crayons when [he or she] returns to draw?" In the two languages with formal markers for false beliefs, the verb *think* in the first question provided an explicit linguistic cue of the false belief state. The critical question is: Does the presence of formal markers for false belief states in a language facilitate understanding of these states (e.g., Experimenter 2 would expect to find the crayons in the crayon box)? Furthermore, is it necessary for the explicit marker to be present in the immediate language use context for it to improve understanding of false belief states? According to the original version of the Whorfian hypothesis, the grammar of a language predisposes its users to a certain pattern of cognition irrespective of whether the grammatical feature is present in the immediate communication context.

If having formal grammatical markers for false beliefs in one's own language improves understanding of false belief states, Turkish and PR Spanish speakers and Turkish speakers should do better than BR Portuguese speakers and English speakers on the comprehension task. In addition, if false belief markers help by improving children's general ability to understand false belief states, irrespective of the language used in any particular case, Turkish and PR Spanish speakers should do better than BR Portuguese speakers and English speakers on the general question about false beliefs ("Where is [Experimenter 2] going to look for the crayons?"), as well as the explicitly marked question ("Where does [Experimenter 2] think the crayons are?"). However, if the grammatical markers for false belief states help only locally, without influencing reasoning in a more general way, the Turkish and PR Spanish speakers should outperform the BR Portuguese speakers and English speakers only when the explicitly marked question was asked. In this study, only a local effect of explicit grammatical markers was found.

The results indicate that the presence of a formal grammatical marker of false belief states in one's language facilitates false belief understanding. Specifically, only 37% of the BR Portuguese- or English-speaking children (children who spoke unmarked languages) answered most of the false belief comprehension questions correctly. In contrast, 71% of the Turkish- and PR Spanish-speaking children (children who spoke marked languages) answered most of the false belief questions correctly when they responded to the *marked* (*think*) questions.

The results also show that marking for false belief in a language has a local rather than a general effect. When the Turkish- and PR Spanish-speaking children heard the unmarked (*look*) questions, only 32% answered most of the false belief questions correctly.

CONCLUSION

Consistent with the linguistic relativity hypothesis, there is evidence that some grammatical properties of a language embody a distinctive cultural worldview. However, the strong claim that the grammar of a language *shapes* its speakers' thought processes lacks empirical support. The lack of clear support for the lin-

guistic determinism hypothesis highlights the need to explore alternative ways of conceptualizing the relationship of language, cognition, and culture.

Effects of Linguistic Encoding

The linguistic determinism hypothesis is not the only way to formulate the relation of language and thought. Whorf's primary concern was how *structural differences among languages* (independent of cultural experiences) predispose users of different languages to highly patterned, systematic, and distinctive thought processes. It is conceivable that the Whorfian hypothesis (1956) is incorrect, and that language (in its generic sense) importantly affects cognition. Indeed, there is considerable evidence that language use influences (1) problem solving (how an object is labeled can affect the way it is used in a problem-solving task; e.g., Ranken, 1963), (2) decision making (the verbal framing of a formally identical decision problem can result in different decisions; e.g., Kahneman & Tversky, 1984), and (3) memory performance (describing a human face may distort accuracy in a delayed recognition test; e.g., Schooler & Engstler-Schooler, 1990).

What is distinctive and interesting about the studies that show clear effects of language on some cognitive process is that, in one way or another, they all involve effects resulting from *the use of language to represent a state of affairs*. This critical commonality leads to an alternative formulation of the relation of language and cognition: Languages with different structural properties afford different tools for characterizing a state of affairs. A language has important cognitive consequences only when its structural features or referring expressions are applied in the immediate language use context (Chiu et al., 1999; Krauss & Chiu, 1998). The result of the false beliefs study reviewed earlier is consistent with this formulation: Among Turkish- and PR Spanish-speaking children, comprehension of false belief states improved only when the comprehension question included an explicit linguistic marker of false belief states.

Recoding interference may explain the effects of linguistic encoding on how a state of affairs is perceived, experienced, and remembered. Schooler and Engstler-Schooler (1990) proposed a recoding interference hypothesis to

account for the memory effects of linguistic encoding. According to this hypothesis, the same state of affairs can be encoded in both verbal and visual representational formats. For example, an eyewitness in a crime scene may visualize the face of a suspect or describe it.

The use of a particular referring expression may evoke an online linguistic representation of the referent that colors the immediate perception of the referent. When it is difficult to verbalize a state of affairs, representations in the verbal and visual formats may contain different information. In the previous example, the verbal description of the face and the visual image of it may contain different information. Under such circumstances, competition may occur between the two forms of representations, and subsequent memory representation of the referent may be assimilated into its linguistic representation (Chiu, Krauss, & Lau, 1998).

In a series of experiments that tested this hypothesis, Schooler and his associates (Schooler & Engstler-Schooler, 1990; Fallshore & Schooler, 1995) had participants either describe or simply visualize a face they had seen. Participants who described the face were *less* able to recognize the face in a delayed recognition test compared to those who had seen the face and visualized it. Featural information about faces is easier to verbalize than configural information (Fallshore & Schooler, 1995). Thus, it is possible that describing a face evoked relatively feature-based representations, whereas perceptually processing the same face created representations that were relatively configuration-based. When the participants recalled the face in a delayed memory task, the verbal representation may have competed with the visual representation and lowered recognition accuracy (Schooler & Engstler-Schooler, 1990).

Recoding interference may also account for some variations between language groups in referent perception and memory. Language is a system of representational symbols; humans use language to represent both immediate events (e.g., "I am hungry now") and non-immediate events (e.g., "Dov and Dre gave birth to happy Ilana in the summer of 2004") (D'Andrade, 2002). As a representation system, language possesses an important property: Speakers of a language can use different referring expressions to indicate the same referent (people with low IQs may be referred to as

mentally retarded or intellectually challenged). Some referring expressions (e.g., *a license* or *a permit*) are semantically identical and evoke similar representations of the referent, whereas others carry very different connotations (e.g., *a failure* vs. *a setback*). Because languages vary in their vocabulary for referring to the same referent, using different languages to characterize the same referent may evoke or create different linguistic and memory representations of the same referent. In the following subsections, we illustrate this argument with three research examples: color codability and color memory, person memory, and figurative encoding of time.

Color Codability and Color Cognition

Color codability refers to the availability of a linguistic code in a language that allows a color to be expressed easily, rapidly, briefly, and uniformly. The effects of color codability meet the criteria thought to be necessary to test the Whorfian hypothesis (see Rosch, 1987). First, variations in color vocabulary can be readily found in natural languages. Second, investigators can measure the physical units of colors (e.g., wavelength) independent of how colors are coded in different languages. Third, members in different language communities should have more or less equivalent experiences with colors. Thus, difference in color memory across people in different language communities should be attributed not to their difference in experience with colors but to the variations in color codability across languages. Finally, nonlinguistic measures of color cognition—color perception, color memory—are available.

Our review of the research literature on the perceptual and memory effects of color codability leads to the following conclusions. First, the properties of the visual system may limit the range of language's effects on color categorization. For example, no language has color categories that include two color spaces (e.g., yellow and blue) and exclude the connecting color space (e.g., green) (Davidoff, 2001). Second, within the constraints imposed by the visual system and the structure of the color space, different languages partition the color space differently (Roberson, Davies, & Davidoff, 2000, Experiment 1a). Third, when a color term is used to label a color, a linguistic representation of the color is created, which may bias the immediate perception and subse-

quent memory of the color. Fourth, variations in the availability of basic color terms across languages may produce different perceptions and memories of the color. Finally, although speakers of two languages with markedly different color vocabularies may see and remember the same colors differently, the differences in color perception or memory between these two language groups would disappear when linguistic encoding of colors is prohibited.

As a reaction to the linguistic determinism hypothesis, some researchers have sought to demonstrate the presence of a universal perceptual order, independent of language. Findings from the early studies seemed to support a view of the "universal evolution" of color terminology (Berlin & Kay, 1969) that can be mapped onto the neurophysiological substrate of color perception (Kay & McDaniel, 1978). Other studies (e.g., Heider, 1972) conducted at about the same time showed that speakers of different languages have better memory for focal colors (paradigm exemplars of basic colors) than for nonfocal colors, and language has no effect on color memory. In a study of 24 languages, Heider found that focal colors, compared to nonfocal colors, are named more rapidly and given shorter names, indicating that focal colors are more codable than nonfocal ones. Heider also found that although there are only two color terms in Dugum Dani (the language of a Stone Age tribe in Irian Jaya), Dugum Dani-speakers have better recognition memory for focal colors than for nonfocal colors. Based on these results, Heider (1972; Rosch, 1973) concluded that the availability of an explicit linguistic code in one's language has no effect on color memory. Instead, some universal perceptual-cognitive processes underlying the internal structure of color categories mediate both color naming and color memory.

The presence of a universal perceptual order leaves no room for any color codability effects on color perception and memory. However, later studies showed that although the properties of the human visual system may limit the range of cognitive effects of color codability, the evidence for the presence of a universal perceptual order is not convincing. Other researchers also found that speakers of different languages partition the color spectrum slightly differently, and that the way the spectrum is partitioned in a language seems to have some important cognitive consequences on color perception and memory.

In reaction to Heider's claim (1972) that focal colors are remembered better than nonfocal ones in all language groups, Lucy and Shweder (1979) argued that the focal colors used in Heider's experiments had higher perceptual salience than did the nonfocal colors. The inherent perceptual salience of focal colors might have given focal colors certain perceptual advantage over the nonfocal colors in the memory test. In the experiments conducted by Lucy and Shweder (1979; see also Garro, 1986; Lucy & Shweder, 1988), after controlling for perceptual salience, focal and nonfocal colors had the same level of recognition accuracy.

Roberson et al. (2000) also suspect that in Heider's (1972) study, the memory advantage of focal colors for Dugum Dani speakers was due to the participants' tendency to choose a focal color in error for a nonfocal color. When monolingual Berinmo speakers were tested, there was also a memory advantage for focal over nonfocal colors. However, when the aforementioned response bias was corrected, the memory advantage disappeared (Roberson et al., 2000, Experiment 2a). In addition, Berinmo speakers learned to associate a nonfocal color with a picture just as fast as they associated a focal color to a picture (Roberson et al., 2000, Experiment 3b). These findings question whether color focality completely determines color memory in all language groups.

To show that the color vocabulary in a language can influence color memory, researchers have sought to establish the correspondence between how similarly two colors are named in a language, and how likely speakers of the language would confuse the two colors in a delayed recognition memory test. If color vocabulary affects color perception, speakers of the language would find it harder to differentiate between two colors if they were named the same way in the language than if they were named differently.

Although the early findings showed that variations in the way the color space is partitioned in a language seem to have little effect on color memory, subsequent studies revealed some effects of linguistic encoding on color perception and color memory. In the first cross-language study of color codability effect, Heider and Olivier (1972) asked their informants in two language groups (English-speaking Americans, and Dugum Dani) to perform a color-naming task and a color-recognition task. American English has 11 ba-

sic color terms, and Dugum Dani has only two achromatic terms for color. A similarity matrix for color naming and a similarity matrix for color recognition were constructed for each language group. The color-naming matrices were constructed from how often the informants gave different colors the same name, and the color recognition matrices were constructed from how frequently the informants confused one color with another in the recognition task. Multidimensional scaling performed on the four similarity matrices revealed marked differences between the two naming matrices, indicating that the stimulus colors are represented *very differently* in the two languages. However, the two memory matrices were almost identical, indicating that the two language groups have *very similar* memory representations of the stimulus colors.

However, a recent replication of the Heider and Olivier (1972) study found some effects of color codability on color memory. The participants in this study (Roberson et al., 2000, Experiment 1a) were native English speakers and monolingual Berinmo speakers from three villages in Papua, New Guinea. There are five basic color terms in Berinmo, which do not map directly onto the basic color terms in English. The investigators used multidimensional scaling to estimate the probabilities that each pair of different colors in the stimulus array would be confused in Berinmo naming, Berinmo memory, English naming, and English memory. If two colors were likely to be confused in Berinmo naming, they were also likely to be confused in Berinmo memory ($r = .54$). However, the correspondence between Berinmo memory and English memory patterns was also significant: If two colors were likely to be confused in Berinmo memory, then they were also likely to be confused in English memory ($r = .44$). More importantly, the correlation of .54 was reliably higher than the correlation of .44, indicating that the Berinmo patterns of naming and memory were more closely matched than were Berinmo memory and English memory patterns.

Another cross-language study also provided evidence for the effect of color codability on color perception. In this study, Kay and Kempton (1984, Study 1) presented three color chips at a time to native speakers of English and speakers of Tarahumara (a Uto-Aztecan language of northern Mexico), and had them judge the similarity or difference of the three

colors. Unlike English, Tarahumara lacks the lexical distinction between the color categories of “green” and “blue.” When the participants’ judgments were compared to the physical distance of the stimuli in terms of their wavelengths, the English-speaking participants, but not Tarahumara-speaking ones, systematically overestimated the distance between two colors when the green–blue color boundary passed between them.

However, Kay and Kempton (1984) believe that the English-speaking participants might have used a naming strategy when they were performing the judgment task. For instance, they might have labeled the color left of the green–blue lexical category boundary “green” and the two colors to the right of the boundary “blue.” Due to recoding interference, they overestimated the perceptual distance between the first color and other colors. However, the Tarahumara-speaking participants could not use this naming strategy, because their language lacks the lexical distinction between the color categories of “green” and “blue.”

Kay and Kempton’s (1984) reasoning is consistent with the findings from an earlier study of linguistic encoding and color experience. In this study, Thomas and DeCapito (1966) trained their participants to emit a finger-lift response to greenish-blue light with the wavelength of 490 μm and later tested their generalization gradient. Participants in the named condition were led to label the 490 μm chromatic light either as “green” or as “blue” when it was presented, whereas participants in the control condition were not. Participants who had labeled the colored light “green” showed stronger generalization responses to wavelengths greater than 495 μm (the wavelengths of greenish light) compared to the participants who had labeled it “blue.” They also exhibited weaker generalization responses to wavelengths shorter than 485 μm (wavelengths of bluish light). Participants in the control condition yielded a generalization gradient intermediate between the two groups.

To test their idea directly, Kay and Kempton (1984, Study 2) induced English-speaking participants to use both verbal labels (“blue” and “green”) to encode the same color. First, the participants saw the target color with a greener color, and they spontaneously encoded the target color as the “bluer” color. Next, they saw the same target color with a bluer color, and spontaneously encoded the target color as the

“greener” color. Following this, the participants evaluated the perceptual distances between the target color, the greener color, and the bluer color. Because the target color was encoded both as a bluer color (when it was paired with the greener color) and a greener color (when it was paired with the bluer color), the effects of the two encodings cancelled out each other. Under this circumstance, the English-speaking participants’ judgments were similar to those of the Tarahumara speakers, and corresponded closely with the physical distance of the colors.

Roberson et al. (2000) reported similar findings in a conceptual replication of the Kay and Kempton (1984) experiments. The participants in the Roberson et al.’s experiments were English speakers and Berinmo speakers. Like Tarahumara, Berinmo makes no lexical distinction between “blue” and “green” colors. However, English lacks linguistic labels that refer to *nol* and *wor* colors in Tarahumara. When asked to judge the perceptual similarity between pairs of colors, English speakers judged two colors across the green–blue boundary as more dissimilar to the two colors within the green or blue category. However, they did not show such categorical perception for colors across the *nol*–*wor* boundary. The reverse was true for the Berinmo speakers. Similar results were obtained among both English speakers and Berinmo speakers in color category learning and color memory. More important, in a subsequent color memory study, Roberson and Davidoff (2000) tested the effect of articulation suppression on color memory. The research participants were Berinmo speakers. In this study, when a verbal interference procedure was introduced to prevent subvocal encoding of the stimuli, the cross-category advantage in color memory was removed.

In short, variations in the availability of basic color terms across languages may produce different perceptions and memories of color. Thus, speakers of two languages with markedly different color vocabularies may see and remember the same colors differently. However, such cognitive differences seem to be mediated by recoding interference, and would disappear when linguistic encoding of colors is prohibited.

Person Memory

Analogous language effects have been found in studies of social memory. In one study,

Hoffman, Lau, and Johnson (1986) presented to their Chinese–English bilingual participants and native English-speaking participants personality descriptions about several target persons. Some descriptions had high Chinese codability: The targets could be coded in a brief Chinese personality term (*shi gu*) that has no equivalent translations in English, or in more clumsy English expressions. The remaining ones had high English codability: The targets could be coded in a brief English personality term (“liberal”) that has no equivalent Chinese translations, or in more clumsy Chinese expressions. The Chinese–English bilinguals either read a Chinese version of the personality descriptions and were encouraged to think in Chinese, or read an English version of the same descriptions and were encouraged to think in English. The English-speaking participants read the English version of the descriptions. Five days later, all participants returned for the second session to make further inferences about the targets in the character descriptions. In response to descriptions of high Chinese codability, the Chinese–English bilinguals using Chinese, compared to the Chinese–English bilinguals using English and the English speakers, made more inferences that were congruent with the brief Chinese personality terms. They also made fewer inferences that were congruent with the brief English personality terms in response to the descriptions with high English codability.

In short, people use economical terms in their language to encode person information. The lexical term used to characterize person information may influence how the information is represented subsequently.

Figurative Speech

Members of each culture have certain characteristic ways of describing events. The use of widely shared figurative descriptions of universal experiences (e.g., the experience of time) offers a good illustration of the social-cognitive processes implicated in the relationship of language use and cognition. Recall that Whorf (1956) believed that some grammatical features in SAE languages (such as the three-tense system of verbs and the absence of formal grammatical markers for real and imaginary plurals) predispose speakers of SAE languages to represent time as a linear continuum that can be conveniently dissected into discrete

units (years, days, minutes, or milliseconds). Instead of focusing on the cognitive consequences of the grammatical features of a language, some researchers have investigated *what* the most coherent figurative expressions of time are in a particular language, and *how* they affect the language group’s experience of time. This research shows that different linguistic groups have developed different characteristic figurative expressions for encoding time. When a figurative expression is used to characterize time, it evokes a linguistic representation that embodies the figurative meanings in the expression. This representation may in turn color the way the speaker experiences time.

Cultures differ in how time is represented metaphorically. In a cross-linguistic study, Zhou (2004) found that the most coherent cluster of time metaphors in the English language represents time as a moving object, and that the one in the Chinese language represents time as a container. She collected 140 Chinese and 131 English time metaphors from native Chinese and English speakers, and from several dictionaries of quotations in the two languages. Next, she had Chinese and English speakers judge the appropriateness of the metaphors in their language. Factor analyses performed on the appropriateness ratings showed that in the English language, metaphors representing time as bounded objects traveling speedily in space (e.g., winged chariot) accounted for 13.7% of the variance in the appropriateness ratings. These metaphorical representations render the perception of time as something that is meant to be caught, yet difficult to catch. Other clusters of time metaphors each accounted for less than 5% of the variance.

In the Chinese language, metaphors that represent time as a boundless bearer of undefined or ill-defined objects, memories, and emotions (e.g., container, ocean) accounted for 13.5% of the variance of the appropriateness ratings (other clusters of time each accounted for less than 6% of the variance). These metaphors render the perception of time as a boundless container that extends in space, with an unlimited capacity for carrying human memories, experiences, and emotions.

English and Chinese speakers also use different directional metaphors to talk about time. For example, English speakers prefer using front–back terms when they talk about time (e.g., ahead of time, behind schedule). In contrast, Chinese speakers prefer using up–down

terms to describe time, referring to yesterday as *one day up* and tomorrow as *one day down*, for example (Boroditsky, 2001).

Research has shown that individuals can process the metaphorical meaning conveyed in a figurative expression at least as efficiently as they process the meaning conveyed in a literal expression (Glucksberg, 2001). In one experiment, Glucksberg had participants make speeded judgments of whether utterances such as “Some lawyers are sharks” are true or false. Participants who answered “no” responded to the utterances’ literal meanings and those who answered “yes” responded to the utterances’ figurative meanings. Affirmative responses were faster than negative ones, indicating that the figurative meanings were processed more efficiently than were the literal meanings.

Moreover, encoding an object with a figurative (vs. literal) expression may lead to memory distortion of the object in the direction of the figurative expression (Lau, Chiu, & Lee, 2001). For example, when a triangle is presented, individuals who have been led to describe it figuratively (“It looks like a mountain”) are less able to recognize the figure in a delayed memory test, compared to those who have been led to describe it literally (“It is a triangle”).

Similarly, encoding time with a figurative expression may also influence how time is experienced. In a series of experiments, Boroditsky (2001) demonstrates how activating time metaphors in a language may influence its speakers’ experience of time. In one experiment, English and Chinese speakers answered a true–false question about time (e.g., March comes earlier than April) after they were primed with the front–back relation (the vehicle of the dominant directional metaphor for time in English) or the up–down relation (the vehicle of the dominant directional metaphor for time in Chinese). The front–back and the up–down primes consisted of two different sets of true–false questions (e.g., “The black worm is ahead of the white worm” vs. “The black ball is above the white ball”). As expected, for the English speakers, the front–back primes produced faster response to the time question than did the up–down primes, and the reverse was true for the Chinese speakers. Furthermore, in the same series of experiments, after native English speakers had been trained to use the up–down metaphor for time, their response pattern looked like that of Chinese speakers. Appar-

ently, the dominant metaphor for time in a language community allows its members to process temporal information efficiently. When the metaphor is activated, people use it as a tool to process temporal information.

Conclusion

The research findings are consistent with the propositions mentioned earlier in this chapter. First, speakers use the characteristic ways of referring to a state of affairs in their language as linguistic tools to encode experiences and express thoughts. When (and only when) these tools are used to characterize certain state of affairs, they influence cognitions by evoking or creating a linguistic representation that competes with and overshadows the perceptual representation of that state of affairs.

Communication and Cognition

Language is not just a collection of words and rules. It is a *communal tool kit* that individuals in a speech community use to construct meanings (Bruner, 1990; Semin, 1998). A speech community shares not only the rules of a language but also common understandings of its use and interpretation (Brenneis, 2002). When individuals translate a thought into external speech, they must cast it in a form that is appropriate for linguistic operations and pertinent to the communication function (Langacker, 1976). The lexical terms in a language limit the ways a thought can be expressed verbally, and so do the contexts of language use, which include the ground rules and assumptions that govern usage, audience design, and the immediate, ongoing, and emerging properties of the communication situation (Krauss & Chiu, 1998).

The cognitive consequences of communication received some attention in early color memory studies. Lantz and Strefflre (1964) argued that color codability predicts color memory only when color codability reflects how easy it is to describe the color accurately to an intended audience. To test this idea, they asked a group of participants (the encoders) to name an array of colors. Next, another group of participants (the decoders) were asked to identify the color associated with each of the color names generated by the first group of participants. From the decoders’ performance, the investigators derived a communicability score for

each color. Finally, they measured the memorability of each color by administering a recognition memory task to a third group of participants. Colors that were more communicable were easier to recognize.

In another study, communication accuracy and recognizability data were collected for the Farnsworth–Munsell color chips from native Spanish speakers and native speakers of Yucatec, a Mayan language (Steffle, Vales, & Morley, 1966). The correlation between communication accuracy and recognition accuracy was .45 in the Yucatec-speaking sample and .59 in the Spanish-speaking sample. Both correlations were statistically reliable. However, communication accuracy in Spanish and communication accuracy in Yucatec were uncorrelated, indicating colors that are easy to communicate in one language community are not necessarily so in another. This finding also eliminates the alternative explanation that communicable colors are focal colors. Other studies also found that easily communicated colors in one language community are also easy to remember in that community (see also Garro, 1986; Lucy & Shweder, 1979, 1988).

How frequently different colors are mentioned in communication may explain the positive correlation of color communicability and recognizability. There may be high consensus in the language community on the referring expressions for colors that are frequently referenced in communication. The established referential communication norms for these colors may render them more communicable than other colors. Meanwhile, people may have better memory for the colors that they frequently encounter and talk about (Lau, Lee, & Chiu, 2004).

Construction of Shared Reality

Sperber (1996) suggests that the best way to study how culture spreads and evolves is by examining how shared representations “are cognized by individuals and how they are communicated within a group” (p. 97). If any state of affairs can be described differently, how do people collaboratively establish its referring expression and consensual meaning?

Some researchers have examined how shared reality arises as communicators tune their message to the assumed beliefs and attitudes of the addressee. This research reveals that speakers estimate their addressee’s knowledge about a

referent when they formulate referring expressions (Clark & Carlson, 1982; Clark & Marshall, 1981; Clark & Murphy, 1982; Clark, Schreuder, & Buttrick, 1983; Krauss & Fussell, 1991, 1996; Krauss, Fussell, & Chen, 1995). Expressions tend to be briefer when the addressee is estimated to be knowledgeable about the referent, and vice versa (Fussell & Krauss, 1991, 1992; Lau, Chiu, & Hong, 2001). In addition, speakers tend to include in their communicative message expressions that are part of the established common ground (Fussell & Krauss, 1989a, 1989b; Krauss & Glucksberg, 1977; Krauss, Vivekananthan, & Weinheimer, 1968). Furthermore, when speakers learn that their addressee has a positive or negative attitude toward a target person, they would tune their descriptions of the target person in the direction of the addressee’s attitude toward the target person. Moreover, the speakers’ subsequent impressions of the target person become evaluatively consistent with the addressee’s attitudes (Higgins & McCann, 1984; Higgins, McCann, & Fondacaro, 1982; McCann, Higgins, & Fondacaro, 1991).

The processes through which dyadic communication produces shared representations between two individuals may mediate the emergence of spatial distributions of shared representations in a collective, which in turn may lead to formation of complex systems of social representations, often referred to as cultures. According to the dynamic social impact theory (Latané, 1996), physical proximity increases the opportunity to communicate: People are more likely to communicate with people in the same neighborhood or workplace than with people living far away. When people communicate with others, shared representations are established. As communication continues, there is a tendency for sets of beliefs, values, and practices to become spatially differentiated (or clustered). At the same time, within a particular clustered location, previously unrelated beliefs, values, or practices become associated (or correlated) and relatively homogeneous (or consolidated; Brauer, Judd, & Jacquelin, 2001). Although consolidation could ultimately result in complete amalgamation, clustering protects minorities from majority influence, thus ensuring continuing diversity.

To simulate the hypothesized processes of culture formation, Latané and his colleagues (Latané & Bourgeois, 1996; Latané & L’Herrou, 1996) organized participants into

e-mail groups and informed them of the majority opinions. Each participant was allowed to communicate by e-mail with only a fixed number of individuals (approximating physical constraints in real life). Over a number of electronic sessions, opinions began to cluster together. Thus, within each communication group, opinions became more homogenous, and previously uncorrelated issues became correlated. However, at the end of the studies, even with incentives to agree with the opinions of the majority, there still remained pockets of minority opinions.

Similar results were obtained in a 3-year longitudinal study of political socialization of business and social science students (Guimond & Palmer, 1985). In this study, over time, social sciences students developed a shared, coherent perspective about social problems. They became more likely than business students to attribute poverty and unemployment to systemic factors. Furthermore, previously uncorrelated beliefs about the causes of poverty became related in the third year.

Summary

Language is not just a collection of symbols and formal rules; it is a framework for action in a language community. The use of language in human communication plays an important role in the development of shared cognitive styles and shared cognitions, which are core elements of culture. Language enables culture, but it does not determine the course of its development (Bruner, 1990).

The role of language use in cultural processes can be summarized as follows:

1. Language encodes cultural meanings. The characteristic expressions in a language afford economical ways of characterizing experiences and expressing thoughts. These expressions are likely to be used in everyday communication.
2. Using language to characterize a state of affairs may evoke or create linguistic representations that compete with and overshadow the perceptual representations of that state of affairs.
3. A speech community shares the formal rules of a language, as well as the ground rules and assumptions that underlie language usage. The contexts of language use (e.g., audience design) influence the forms linguistic

representations of certain state of affairs will take. Through communication, private cognitions are made public and directed toward a shared representation of the referent (Schegloff, 1991).

CONCLUSIONS AND FUTURE DIRECTIONS

The preceding analysis of the relationship of language and culture embodies a constructivist view of culture (see Chiu & Chen, 2004; Ng, Chiu, & Candlin, 2004). In this view, through the use of language as discourse, the shared reality expresses itself in communicative actions; that is, language plays a pivotal role in constituting the existing social reality by providing a set of shared symbols for constructing shared meanings.

In a review, Lehman, Chiu, and Schaller (2004) discerned a lopsided emphasis in the psychology literature on cultural differences. Their review reminds researchers of the need for a body of psychological knowledge that explains how discursive practices maintain the stability of a culture, and the role of language use in culture change.

Although cultural psychologists have not done much to uncover language's role in the reproduction and transformation of culture, some investigators have begun to examine how shared ideas are reproduced and propagate through interpersonal communication. The four aspects of this process that have received relatively more research attention are (1) reproduction of conventional cultural knowledge through communication, (2) institutionalization of cultural knowledge in communication practices, (3) language as a carrier of cultural meanings, and (4) language as a marker of cultural identities.

Language Use and Reproduction of Culture

Communication and Reproduction of Conventional Cultural Ideas

Successful reproduction of cultures requires reproduction of shared meanings in communication (Sperber, 1996). In series of experiments, Lyons and Kashima (2001, 2003) found that conventional ideas are more likely to be reproduced in dyadic communication compared to unconventional ones. These findings provide important leads into the discursive foundation

of culture. If conventional ideas are more likely than unconventional ones to be included in communications, they should be more inheritable in cultural transmission. As Sperber (1996, p. 83) puts it, cultural ideas that are “repeatedly communicated and minimally transformed in the process will end up belonging to the culture.”

Institutionalization of Cultural Knowledge

Shared cognitions that emerge from communication are often instituted in communicative practices. For instance, compared to East Asians, European Americans focus their attention more on the object (vs. object–context relation; Masuda & Nisbett, 2001). This cultural difference is instituted in adult–child communication. English-speaking American children use more nouns (which reference objects or abstract entities) and fewer verbs (which describe how the grammatical subject acts upon the external environment or internal state) than do Mandarin-speaking children in China (Tardif, 1996; Tardif, Gelman, & Xu, 1999). Moreover, English-speaking caregivers also emphasize nouns over verbs when they talk to children, whereas Mandarin-speaking caregivers have the reverse trend (Tardif, Shatz, & Naigles, 1998). As another example, the Confucian tradition in Chinese culture emphasizes moral and social standards, and Chinese families often reference such standards in personal storytelling, whereas American families typically use personal storytelling as a medium of entertainment and affirmation (Miller, Wiley, Fung, & Liang, 1997).

Language Activates Cultural Meanings

Because of the close association of language use and culture, the presence of a language may evoke its associated cultural meanings. Earle (1969) reported the first experimental demonstration of language priming effect and found that bilingual Hong Kong Chinese students are less dogmatic when they respond to the Dogmatism Scale (Rokeach, 1960) in English than when they answer the same questionnaire translated into Chinese. Earle proposes that Hong Kong bilinguals, who have learned Chinese and English in distinct settings, can maintain two somewhat differently structured belief systems, reflecting the contexts in which they acquired the two languages and, more gener-

ally, the two language cultures. As such, the Chinese version of the questionnaire activates the more dogmatic Chinese language culture, and the English version activates the less dogmatic English language culture. Similar language-priming effects have been reported among Hong Kong Chinese, Chinese Canadians, and Greek–Dutch bilinguals on spontaneous self-concept, self-esteem, and causal attribution (Bond, 1983; Ross, Xun, & Wilson, 2002; Trafimow, Silverman, Fan, & Law, 1997; Verkuyten & Pouliasi, 2002).

Language as a Marker of Cultural Identity

Language can also be a marker of cultural identity. There is consistent evidence that the language one speaks is an important dimension for both self- and social categorization (Bourhis, Giles, & Tajfel, 1973). Giles, Taylor and their associates compared the relative contributions of language, cultural background, and geographical residence to self- and social categorization in five groups: Welsh bilinguals from South Wales (Giles, Taylor, & Bourhis, 1977), English Canadians, French Canadians (Taylor, Bassili, & Aboud, 1973), Anglo Americans and Franco Americans (Giles, Taylor, Lambert, & Albert, 1976). They found that for all groups, the language spoken was the most salient dimension of self- and ethnic identities.

In addition, listeners’ attitudes toward speakers of certain languages or dialects reflect their evaluations of the relative status of the speakers’ ethnolinguistic group (Brennan & Brennan, 1981; Callan, Gallois, & Forbes, 1983; Genesee & Holobow, 1989; Lyczak, Fu, & Ho, 1976; Mazurkewich, Fister-Stoga, Mawle, Somers, & Thibaudeau, 1986; Sebastian & Ryan, 1985; Tong, Hong, Lee, & Chiu, 1999). Furthermore, although people’s speech styles tend to converge (i.e., to become more like those of their partners), speakers may react to identity-threatening circumstances by accentuating speech and nonverbal differences between themselves and members of the other group (Bourhis et al., 1973; Bourhis & Giles, 1977; Bourhis, Giles, Leyens, & Tajfel, 1979; Taylor & Royer, 1980). Likewise, the presence of the language of an unfriendly out-group may also lead one to affirm the cultural values of one’s own group (Bond & Cheung, 1984; Bond & Yang, 1982; Yang & Bond, 1980).

Finally, speakers tend to describe in-group and out-group behaviors differently. For exam-

ple, speakers spontaneously use more abstract verb phrases (e.g., hate) and fewer concrete verb phrases (e.g., hit) when they describe behaviors of a stereotyped ethnocultural group than when they describe the behaviors of their own group (Hamilton, Gibbons, Stroessner, & Sherman, 1992). Encoding a behavior with an abstract verb implies that the behavior is stable and consistent across situations, whereas encoding a behavior with a concrete verb limits the generality of the behavior to a concrete situation (Semin & Fiedler, 1988, 1991). Thus, this finding suggests that behaviors of stereotyped groups are likely to be linguistically encoded as reflecting abstract qualities of the group members. However, the tendencies to describe the behaviors of out-group members in abstract verb types are not uniform across different types of behavior. Undesirable out-group behaviors tend to be described with abstract verb types, whereas desirable out-group behaviors tend to be described with concrete verb types (Fiedler, Semin, & Finkenauer, 1993; Maass, Milesi, Zabbini, & Stahlberg, 1995; Maass, Salvi, Arcuri, & Semin, 1989). In short, the ways people use language may reinforce cultural stereotypes, as well as the boundary separating their own group from other ethnic groups.

Language and Culture Change

In a relatively impermeable culture, or a culture that has few contacts with other cultures, the communicative mechanisms described in the previous paragraph give rise to a relatively stable cultural tradition. However, even in such relatively closed cultures, changes in the mode and means of production, technology, political system, and interdependence structure may present a need to open negotiation of meanings in public discourse. In a multicultural society, exposure to knowledge from different cultures highlights cultural contrasts and triggers a meaningful negotiation process that fuels culture change (Ota, 2004). The tracking of communicative messages in settings where intercultural contacts are frequent and intense may reveal how language and culture coevolve. For example, as tourists participate in international travel, they are socialized into the reality represented in travel magazines, newspaper travelogues, and televised holiday programs. The language and rhetoric used in these media provide the semiotic materials for analyzing how

the culture and identity of global citizens evolve (Jaworski & Thurlow, 2004).

Indeed, as the speed of globalization accelerates, communicative acts may function like a barometer of culture change. For instance, China has undergone rapid economic and social transformation in the last two decades. How might this transformation change the collectivist values in China? Zhang and Shavitt (2003), who analyzed the values promoted in Chinese advertising, found that both modernity and individualism predominate in current Chinese advertising. In addition, individualism and modern values are more pervasive in magazine advertisements (which target young consumers) than in television commercials (which target older consumers). All these changes suggest that after half a century of psychological research and intense debates on language's role in cognitive and cultural processes, the field is still open, with exciting territories that remain to be discovered and explored.

PART VI

EMOTION AND MOTIVATION

CHAPTER 28

Culture and Subjective Well-Being

WILLIAM TOV
ED DIENER

With great perseverance
He meditates, seeking
Freedom and happiness.
—THE BUDDHA, Chapter 2, *The Dhammapada*

Over 2,000 years ago, the Buddha perceived suffering to be the nature of existence. But for him, the attainment of nirvana was not simply a break from this cycle of suffering, it was also a return to true bliss. Although it was not the direct purpose of meditation, happiness was certainly an important consequence, and a critical topic in Buddhist philosophy (Gaskins, 1999). Across time and cultures, generations of people have in their own way reflected upon the question of happiness. As long as it has been pondered, it may come as a surprise that the scientific study of happiness, or subjective

well-being (SWB; E. Diener, 1984) has advanced only recently.

One of the challenges has been defining happiness in a way that enables it to be measured. Given that conceptions of happiness may vary across different societies, a number of questions arise regarding *how* culture influences the idea and experience of happiness. Do the structure and content of SWB differ? Do certain cultures emphasize some components more than others? Are the correlates and causes of happiness similar across cultures? Do people react differently to the expe-

rience of well-being (e.g., when they feel pleasant affect)?

As it has been studied over the past two decades, SWB involves frequent pleasant emotion, infrequent unpleasant emotion, and life satisfaction (LS). The first two components are affective; the last is a cognitive evaluation. These three components are not the only elements of SWB. Happiness also can be said to consist of other dimensions, such as meaning and purpose in life. However, in this review we focus on LS, pleasant affect, and unpleasant affect, in part because these constructs have been researched more frequently across cultures. Furthermore, these components of SWB are major focal points that allow for a certain degree of precision in measuring the fuzziest, folk concept of happiness.

WHY STUDY SWB ACROSS CULTURES?

The cross-cultural study of SWB is one indicator of the quality of life in a society. It was once considered taboo to suggest that societies could be evaluated at all (Shweder, 2000). To appraise *any* aspect of a culture was to ignore its worth and integrity. However, this extreme form of cultural relativism has given way to the view that though one must be careful in comparing and evaluating, societies may differ in variables such as health and satisfaction that are desirable in most cultures. It is true that some indicators of life quality may impose values about the good life that are not shared by all people. However, even if SWB is internally framed with respect to each culture, societies could still be evaluated in terms of how well they succeed according to these internal criteria.

Culture and SWB research can also shed light on basic emotional processes. In measuring SWB across various societies, researchers have confronted issues regarding the universality of emotions, and how the representation of emotions in memory is influenced by cultural norms. The field can also add to our understanding of culture. For example, how do cultures differ in their socialization of pleasant and unpleasant affect, and how do emotions contribute to the reinforcement of cultural values and practices? These questions reflect a cultural-psychological perspective. Thus, the topic is of both applied and theoretical importance.

HISTORY OF THIS FIELD OF INQUIRY

Anthropologists adopted cultural relativity as a way of avoiding a Western, ethnocentric bias in observing other cultures. They made the important observation that values and practices might vary across cultures, but this need not imply that some cultures are necessarily better than others. In particular, we should avoid judging other cultures by the standards of our own. However, taken to extremes, cultural relativism would prevent one from saying that Nazi Germany, or Cambodia under the Khmer Rouge, were in many respects undesirable cultures (Edgerton, 1992). This level of extreme value relativity would make cultural psychology irrelevant to public discourse. According to Edgerton, not all practices in a culture are adaptive; some may even be harmful. He defined "maladaptive cultures" as those in which there is rampant dissatisfaction or impaired physical and mental health. Thus, there are certain criteria by which we can judge the success of a culture. As one such criterion, SWB is important because a society functions poorly when a majority of its people are discontent and depressed.

It should be noted that very little quantitative work has examined the well-being of small cultures (e.g., Biswas-Diener, Vittersø, & Diener, 2005), although a number of international surveys of SWB in modern nations have been conducted (e.g., Cantril, 1965; Inglehart, 1990; see Table 28.1). Only recently has research examined the structure and causes of SWB in different cultures. In 1995, for example, E. Diener and M. L. Diener found that self-esteem correlated more strongly with LS in individualist than in collectivist cultures, and that financial satisfaction more strongly predicted LS in poor than in rich nations. Since then, there has been a rapid growth in the field of culture and well-being, and both universal and unique correlates of SWB have been documented. We foresee further growth in this research area in the decade to come.

GENERAL APPROACHES TO CROSS-CULTURAL COMPARISONS OF SWB

The comparisons that researchers make across cultures are guided by their assumptions about the interplay between culture and SWB. We review some of these approaches here.

TABLE 28.1. LS in Various Nations (1999–2002)

Nation	Year	LS	SD	Nation	Year	LS	SD
Puerto Rico	2001	8.49	1.97	Vietnam	2001	6.52	2.06
Denmark	1999	8.24	1.82	Japan	2000	6.48	1.97
Malta	1999	8.21	1.62	Peru	2001	6.44	2.40
Ireland	1999	8.20	1.83	Iran	2000	6.38	2.41
Mexico	2000	8.14	2.35	South Africa	2001	6.31	2.69
Iceland	1999	8.05	1.59	South Korea	2001	6.21	2.32
Austria	1999	8.03	1.92	Poland	1999	6.20	2.53
Northern Ireland	1999	8.00	1.75	Morocco	2001	6.06	2.54
Finland	2000	7.87	1.65	Slovakia	1999	6.03	2.22
Netherlands	1999	7.85	1.34	Estonia	1999	5.93	2.18
Canada	2000	7.85	1.88	Hungary	1999	5.80	2.42
Luxembourg	1999	7.81	1.87	Bosnia-Herzegovina	2001	5.77	2.39
USA	1999	7.66	1.82	Bangladesh	2002	5.77	2.18
Sweden	1999	7.64	1.86	Algeria	2002	5.67	2.86
Venezuela	2000	7.52	2.50	Uganda	2001	5.65	2.47
El Salvador	1999	7.50	2.43	Montenegro	2001	5.64	2.38
Belgium	1999	7.43	2.13	Turkey	2000	5.62	2.79
Germany	1999	7.42	1.96	Serbia	2001	5.62	2.47
Great Britain	1999	7.40	1.94	Jordan	2001	5.60	2.50
Argentina	1999	7.30	2.26	Bulgaria	1999	5.50	2.65
Singapore	2002	7.24	1.80	Egypt	2000	5.36	3.35
Italy	1999	7.17	2.11	Latvia	1999	5.27	2.39
Chile	2000	7.12	2.16	Romania	1999	5.23	2.77
Spain	1999	7.09	1.92	Lithuania	1999	5.20	2.66
Czech Republic	1999	7.06	1.97	Albania	2002	5.17	2.25
Portugal	1999	7.04	1.96	India	2001	5.14	2.23
Israel	2001	7.03	2.17	Macedonia	2001	5.12	2.72
France	1999	7.01	1.99	Pakistan	2001	4.85	1.46
Indonesia	2001	6.96	2.06	Belarus	2000	4.81	2.21
Nigeria	2000	6.87	2.32	Russia	1999	4.56	2.57
Croatia	1999	6.68	2.30	Ukraine	1999	4.56	2.59
Greece	1999	6.67	2.19	Moldova	2000	4.56	2.32
Philippines	2001	6.65	2.53	Zimbabwe	2001	3.95	2.79
China	2001	6.53	2.47	Tanzania	2001	3.87	3.22

Note. LS scores are based on responses to the question, "All things considered, how satisfied are you with your life as a whole now?" on a 10-point scale from 1 (*dissatisfied*) to 10 (*satisfied*). Data from Veenhoven (n.d.).

Dimensional Approach

Some theorists hold that the causes of well-being are fundamentally the same for all people. Ryff and Singer (1998) posited that purpose in life, quality relationships, self-regard, and a sense of mastery are universal features of well-being. Self-determination theorists (Deci & Ryan, 1985; Ryan & Deci, 2000) maintain that well-being hinges on the fulfillment of *innate* psychological needs such as autonomy, competence, and relatedness. If these sources of well-being are universal, they provide dimensions along which we can compare societies. Cultures should differ in SWB to the extent that they provide people with different levels autonomy, meaning, and relationships.

A related perspective is the universalist position on emotions. Drawing on diverse findings, some researchers propose that there are discrete, basic emotions that appear in all cultures (Ekman & Friesen, 1971; Izard & Malatesta, 1987; Plutchik, 1980; Tomkins, 1962, 1963). For example, facial expressions of anger, sadness, and joy appear early in infancy (Izard & Malatesta, 1987) and are easily recognized in many different cultures (Ekman & Friesen, 1971; Ekman et al., 1987). Facial expressions of laughing and crying among congenitally blind infants (Thompson, 1941) suggest that there may be genetic programs directing the expression of emotions. The possibility of biologically based, basic emotions is important, for it implies that we can compare people across so-

cieties on these emotions (however, see Ortony & Turner, 1990, for a critique of the basic emotions concept).

Uniqueness Approach

In contrast to the universalist approach, some ethnographers emphasize emotions as social constructions. According to these researchers, the very concept of emotion may differ across cultures. Lutz (1988) noted that Western ethnopsychologies often view emotions as hidden and private. In contrast, her work in Micronesia revealed that Ifalukian concepts of emotions are more public and relational. Cultures may also differ in their labeling of specific feelings. For example, according to Wierzbicka (1986) there is no word for “disgust” in Polish. Extreme versions of the uniqueness approach hold that emotions are purely a Western idea, and that internal experiences can be represented in countless ways across cultures. More moderate formulations, on the other hand, maintain that biologically based emotions may be universal, but that culture can significantly alter their development and labeling. Thus, although sadness is often considered a basic emotion with recognizable antecedents, the Tahitians do not appear to have such a label for it (Levy, 1982). Instead, they often refer to feelings of sickness or exhaustion, for which the causes are nonspecific. Although the uniqueness approach does not preclude the possibility of making comparisons across cultures (e.g., Wierzbicka, 1986), it takes as its starting point the culturally patterned subtleties of emotional experience.

Identity Approach

Another perspective on universality is that regardless of the specific elements, all cultures enjoy *identical levels* of SWB. Cultures may differ in their values and in the needs they fulfill, but people eventually adapt, leading all societies to be relatively happy. The identity approach likens well-being to a “hedonic treadmill” upon which people run but never change position. Only in cultures that are severely disrupted or experiencing trauma (e.g., warfare or famine) is adaptation impossible, resulting in widespread unhappiness. The identity perspective may sound absurd, but in Table 28.2, diverse groups appear to enjoy somewhat comparable levels of LS. For instance, the Amish, Inughuit,

TABLE 28.2. LS of Selected Groups

Positive groups	LS
<i>Forbes</i> richest Americans ^a	5.8
Pennsylvania Amish ^b	5.8
Inughuit (Inuit group from Northern Greenland) ^c	5.8
East African Maasai ^c	5.4
International college students (47 nations) ^b	4.9
Calcutta slum dwellers ^d	4.6
<i>Neutral point of scale = 4.0</i>	
Groups below neutral	LS
Calcutta sex workers ^d	3.6
Calcutta homeless ^d	3.2
California homeless ^b	2.9

Note. LS scores are based on responses to the statement “You are satisfied with your life,” on a 7-point scale from 1 (*strongly disagree*) to 7 (*strongly agree*).

^a E. Diener, Horwitz, and Emmons (1985); ^b E. Diener and Seligman (2004); ^c Biswas-Diener et al. (2004); ^d Biswas-Diener and Diener (2001).

and Maasai all report LS that is not significantly different from the richest Americans, suggesting that material luxury is not necessary for well-being. All these groups may be meeting needs, such as for social relationships, that are critical for SWB. Thus, important conditions for happiness may be met in nonindustrial societies such as the Maasai. In contrast, the LS of the homeless indicates that not all groups are happy, and that people do not fully adapt to all conditions.

The Middle Path

In this chapter, we take a middle path. We argue that there are some universals, such as the tendency for people to be *slightly* happy, unless they are exposed to harsh conditions. Some variables, such as temperament and positive relationships, influence SWB in all cultures. There may also be common goals, such as the need for respect, that characterize people in all cultures. Furthermore, because cultural influences often permeate national boundaries, cultures are not completely independent of one another. However, each culture also retains unique qualities and should not be compared with others in a careless way. Not all comparisons of SWB are meaningful, because the value placed on certain subjective states, and the labels for them, of-

ten differ. The patterning of well-being may also vary across cultures, making it dangerous to compare variables at a high level of abstraction. Thus, although comparisons are possible, they should only be made with due care to take into account the unique factors present in various societies.

Cultural differences in SWB can be likened to differences between individuals. People can be compared on certain universal features such as height and weight. They can also be compared on factors such as health, but health is made up of many lower-order concepts that may relate to each other differently across individuals. Although societies can be compared in terms of individuals' longevity, patterns of illness differ across cultures. In a similar way, cultures can be compared on SWB, but there are also unique facets of well-being in each society that are best captured by specific descriptions of the local culture.

In the sections that follow, we cover several major topics in culture and SWB research. We begin with the issue of patterning and structure, examining how the elements of SWB cohere across societies. Next, we consider whether cultures differ in mean levels of SWB where the structures can be compared, and what factors might contribute to these differences. We then review various correlates and causes of SWB, showing both similarities and differences in cultural recipes for happiness. Following this discussion, we ask whether SWB leads to the same outcomes in different cultures, or whether there are unique effects that depend on the role of emotions in a culture. Finally, we assess the various challenges involved in measuring SWB across cultures, and the impact that measurement artifacts may have on the findings.

PATTERNING AND STRUCTURE

The validity of cross-cultural comparisons of SWB depends on how it is structured in different societies. If there are both universal and culture-specific emotions, do aggregates such as pleasant and unpleasant affect apply to all cultures? Is the concept of LS understood by people in all societies? Also, do the three components of SWB relate to each other similarly across cultures? We review the research bearing on these issues below.

Levels of Analyses

As discussed earlier, the existence of universal emotions has been debated for some time. Researchers have used a number of methodologies to answer the question of universality, including ethnography, facial expression recognition, and emotion taxonomies. After conducting cross-cultural research on facial expression recognition, Ekman and Friesen (1971; Ekman et al., 1987) suggested that happiness, anger, fear, sadness, and disgust are universal. However, there are also emotions that appear in some cultures but not others. Some appear to be labeling of specific situation–outcome pairings in relation to feelings. In Japan, for example, the term *kanashii* refers specifically to sadness arising from personal loss (Mesquita & Fridja, 1992). Other indigenous emotions seem to be complex blends, such as *aviman* in India, which has been described as “prideful, loving anger” (Scollon, Diener, Oishi, & Biswas-Diener, 2004).

According to Mesquita, Fridja, and Scherer (1997), the debate over universality has hindered culture and emotion research by focusing on the mere presence of certain emotions in a culture rather than on how emotions are “practiced.” They argue that emotional experience is a process that includes appraisal of a situation, physiological reactions, overt behaviors, and other components. What distinguishes one emotion from another is the *pattern* of components. At a general level, universal patterns of emotional experience may exist due to innate, neurophysiological programs. For example, joy may inherently feel pleasant and evoke the urge to laugh or smile. However, at the level of specific components, cultural differences may abound. The *type* of events that elicit joy, or attempts to regulate it, may vary across societies.

The perspective provided by Mesquita et al. (1997) resonates with several lines of research on well-being. In assessing the cross-cultural applicability of pleasant and unpleasant affect, SWB researchers have not only been interested in *which* emotions are present, but also in how frequently they are experienced, how they are patterned, and how norms can shape the structure and composition of pleasant and unpleasant affect. In short, the field of culture and SWB has been concerned as much with the ecology, or practice, of emotions (Mesquita et al., 1997) as with the comparability of SWB across cultures. We see that the distinction be-

tween pleasant and unpleasant affect can be made at a general level, and that there are both similarities and differences in the specific aspects of these emotions.

Structural Evidence

In an early study, Watson, Clark, and Tellegen (1984) found that the mood structure of Japanese participants formed two factors, identifiable as positive and negative affect. This two-factor structure was very similar to that of American participants. Hierarchical cluster analyses of emotion words from the United States, Italy, and China also revealed superordinate groupings of positive and negative emotions (Shaver, Wu, & Schwartz, 1992). Pleasant and unpleasant emotion clusters were also observed in experience sampling data provided by Japanese, Indian, and two American samples (Scollon et al., 2004). Moreover, indigenous emotions that were included in the Japanese and Indian samples did not form separate clusters, but grouped together with the pleasant and unpleasant emotions.

M. L. Diener, Fujita, Kim-Prieto, and E. Diener (2004) studied the frequency of 12 emotions and found that they formed positive and negative clusters in seven regions of the world (Africa, Latin America, East Asia, Southeast Asia, West Asia, Eastern Europe, and Western Europe). Moreover, in virtually all of these regions, a core group of emotions consistently loaded onto either positive or negative clusters; that is, positive emotions included *pleasant*, *cheerful*, and *happy*, whereas negative emotions included *unpleasant*, *sad*, and *angry*. Similarly, Shaver et al. (1992) found that one positive (*joy*) and three negative emotions (*anger*, *sadness*, and *fear*) formed basic-level categories in all three cultures they studied. Thus, when speaking of emotion aggregates, there is compelling evidence that pleasant and unpleasant affect are perceived in all cultures. There is also support for the universality of particular emotions such as joy, anger, and sadness. However, cultural differences may arise regarding more specific emotions. For instance, outside of the core emotions, M. L. Diener et al. (2004) observed differences in how other emotions clustered. *Pride* clustered with positive emotions in Latin America, Western Europe, and East Asia, but with negative emotions in Africa, Southeast Asia, Eastern Europe, and West Asia. *Pride* also aligned with negative emotions among smaller

samples in India and Italy (Scollon et al., 2004; Shaver et al., 1992). These findings should be interpreted cautiously. The simple fact that pride clusters with negative emotions in a culture does not necessarily mean that it is experienced as a negative emotion. In the case of M. L. Diener et al.'s data, the cluster analyses were based on the frequency of experience and included weights for means, standard deviations, and correlations—any of which could have affected how emotion terms clustered. In those regions where *pride* was experienced less frequently, it clustered with the negative emotions, which were generally experienced less often than positive emotions. In contrast, *worry* and *stress* clustered with the positive emotions in Western Europe and East Asia, primarily because they were frequently experienced in those areas. Thus, emotional experience may be universal in some ways but culturally varied in others. Recently, Kuppens, Ceulemans, Timmerman, Diener, and Kim-Prieto (2006) found that although positive and negative affect emerged as strong universal intracultural dimensions, there were also smaller, but significant, nation-level dimensions of emotional experience on which nations could be discriminated.

Differences in the frequency of emotions may be related to cultural norms. For example, cultural norms might make some situations more common than others. Thus, the American cultural environment might afford more opportunities for self-enhancement (and the experience of pride), whereas the Japanese cultural environment might be more conducive to self-criticism (Kitayama, Markus, Matsumoto, & Norasakkunkit, 1997). According to Markus and Kitayama (1994), normative social behavior and cultural models of the self might also shape the desirability of certain emotions. In individualist cultures, pride is an enjoyable emotion that highlights individual achievement, as well as success in meeting the cultural goals of autonomy and independence. However, in collectivist cultures, emotions resulting from sympathy and humility may feel good because they are consistent with the cultural goals of interdependence. Emotions that conflict with these norms may be deemphasized and less frequently experienced. Thus, pride may not be as valued in some collectivist Asian cultures because it is self-focusing and separates the individual from the group (Kitayama & Markus, 2000; Markus & Kitayama, 1994;

Scollon et al., 2004). In a similar way, the Oriyas in India devalue anger, because it is regarded as socially destructive (Menon & Shweder, 1994). On the other hand, shame¹ is viewed as a good emotion for *women* to have, because it is integral to sustaining the patriarchal order of society.

The Oriya case draws attention to *intra*-cultural variation in emotion norms; that is, norms may not apply or be uniformly perceived across all individuals within a culture. Eid and Diener (2001) investigated this issue by examining the desirability and appropriateness of pleasant and unpleasant affect in the United States, Australia, China, and Taiwan. They found that norms for pleasant emotions (e.g., joy, affection, pride, and contentment) were more heterogeneous in China and Taiwan than in the United States and Australia. For instance, the vast majority (83%) of Australians and Americans regarded all four pleasant emotions as appropriate. In contrast, only 9% of Chinese and 32% of Taiwanese felt this way. A majority of the Taiwanese (57%) had mixed feelings about pride, although joy, affection, and contentment were appropriate. A plurality of the Chinese (32%) felt that joy and affection were appropriate, but that pride was clearly inappropriate. Another class of individuals found only among the Chinese (16%) regarded all pleasant emotions as *inappropriate*. These findings suggest that culture may influence emotion norms in two ways. First, cultures may foster unique normative patterns, as observed in the Chinese sample. Second, some patterns may be pan-cultural, but their relative frequency within cultures may differ. All pleasant emotions are clearly favored in the United States and Australia. The ambivalence toward pride in China and Taiwan is consistent with previous research on collectivist Asian cultures.

However, the relation between emotion norms and emotional experience may not always be direct. Recent work by Tsai, Knutson, and Fung (2006) suggests that the emotions people value (ideal affect) are not necessarily the ones they experience most frequently (real affect), although the correlations are moderate. These researchers found that although cultural values predicted the *preference* for high- versus low-arousal pleasant emotions, the reported *frequency* of these emotions was better predicted by personality traits. Furthermore, norms may influence some emotions more than others. M. L. Diener et al. (2004) found that

the correlation between the appropriateness and frequency of an emotion was larger for “secondary” emotions such as pride, guilt, gratitude, and jealousy, than for the core emotions; that is, norms appear to predict more strongly the experience of secondary emotions than the experience of core emotions. Indeed, the main cultural differences in structure were due to how the secondary emotions clustered, and the various geopolitical regions diverged most in the frequency of these emotions. For example, people from Southeast Asia more frequently reported experiences of guilt and shame, whereas people from Latin America registered more pride than people from other areas. Also, norms for pride and guilt were more variable across cultures than norms for other emotions (Eid & Diener, 2001). Differences in the experience of peripheral emotions, such as pride, may reflect cultural ideologies regarding attribution styles, such as whether success should be attributed to the self or to the situation (Heine, Lehman, Markus, & Kitayama, 1999). In contrast, a core emotion such as happiness is much broader and may tend to follow from a range of outcomes that are considered good in each culture, so that valuing general happiness is likely to be more common across cultures.

In addition to emotions, there is also support for similarity in the structure of LS across cultures. Vittersø, Røysamb, and Diener (2002) carried out confirmatory factor analyses on the five items of the Satisfaction with Life Scale (SWLS; E. Diener, Emmons, Larsen, & Griffin, 1985) and found that a one-factor model fit the data reasonably well in 41 nations. In all nations, the comparative fit index was above .90. This finding suggests that the SWLS measures a single construct, and that the concept of “life satisfaction” may be similarly understood across a wide range of cultures. That is not to say that the *criteria* for LS are universal; rather, people in a number of diverse cultures appear to react to queries about LS in a consistent way.

The Relation between Emotions and LS

Although the structure of emotions is somewhat consistent across cultures, and the items of the SWLS also seem to cohere reliably, the relation between emotions and LS may vary across cultures (Schimmack, Radhakrishnan, Oishi, Dzokoto, & Ahadi, 2002; Suh, Diener, Oishi, & Triandis, 1998). Suh et al. examined

the relation between LS and affect balance (the difference in frequency of pleasant and unpleasant affect). They found that LS and affect balance correlated positively across 40 nations; thus, experiencing more pleasant than unpleasant affect predicted greater LS across cultures. However, the correlations were stronger in more individualist countries. Suh et al. (Study 2) also assessed cultural norms for LS by asking participants what they perceived to be the ideal level of LS in their culture. When LS was predicted from both emotions and perceived norms for LS, the former was highly predictive among individualist cultures, accounting for 76% of the variance in LS. In contrast, norms and emotions were equally predictive of LS in collectivist cultures, accounting for 39% and 40% of the variance, respectively. A possible explanation is that in individualist cultures, where personal goals and preferences are emphasized, emotions may be important because one's own feelings are often a relevant factor in one's judgments. However, in collectivist cultures, there may be a greater tendency to use norms as a guide for one's attitudes and behavior, and not be the "nail that stands out." Thus, when judging their LS, people from collectivist cultures might weigh norms at least as much as their own emotions. This raises the possibility that collectivists are simply responding in a normatively appropriate manner. Though it is difficult to rule out this alternative explanation, other data suggest that this is not invariably the case. For example, perceived norms for negative emotions were not reliably related to self-reported frequency of these emotions among Chinese and Taiwanese respondents (Eid & Diener, 2001; we discuss further methodological issues later in the chapter).

Conclusion

There are universals in the structure of SWB that make some comparisons possible. Pleasant affect, unpleasant affect, and LS are not unfamiliar concepts to most of the world's people. Nevertheless, to some degree, cultural norms shape which emotions are pleasant and unpleasant to feel. Therefore, when using aggregates such as pleasant and unpleasant affect, one must be careful, because specific emotions may cohere differently within the larger aggregate. The comparison of emotion aggregates should only be made with emotions that cohere similarly in each culture. Finally, emotions may

be more relevant to global LS in individualist cultures, where internal experience is highly valued. This difference highlights the importance of measuring emotions and LS as separate components of SWB; that is affective and cognitive evaluations of well-being reflect different aspects of the superordinate construct of SWB.

COMPARING THE MEAN LEVELS OF SWB OF CULTURES

In discussing the happiness of societies, it may seem surprising that a majority of people in the world report being happy. That is not to say that all of humanity is in a state of elation or jubilation, or that there is no variation across cultures in overall levels of well-being. A wide range of economic, sociocultural, and biological factors may affect the mean level of subjective well-being in a society, but in most cultures, the mean level is above neutral.

Most People Are Happy

A study involving 31 nations ($N = 13,118$) revealed that 63% of men and 70% of women reported positive levels of LS (E. Diener & Diener, 1995). These findings may be limited, in that many of the nations studied were fairly industrialized, and most of the participants were college students. However, E. Diener and Diener (1996) plotted the distribution of mean SWB responses from nationally representative samples from 43 nations and found that 86% were above the neutral point (see Table 28.1 for more data based on representative probability samples). Furthermore, positive levels of well-being appear to be fairly stable over time. National levels of SWB in the United States, Japan, and France fluctuated over a 46-year period but never dipped below neutral (Veenhoven, 1993). Positive levels of well-being have also been observed among smaller, nonindustrialized societies such as the Maasai in Kenya, the Inughuit in Greenland, and the Amish in the United States (Biswas-Diener et al., 2005).

The claim that "most people are happy" is not meant to deny that there remains significant ill-being and suffering in the world. It is important to note that data from the poorest nations of the world (e.g., Rwanda, Mozambique, and Afghanistan) are often lacking (see Table 28.1). Moreover, although most people

report levels of SWB above the midpoint, very few report being extremely happy. Only 4% of E. Diener and Diener's (1995) sample were at the top of the LS scale. Similarly, although the Maasai, Inughuit, and Amish were all significantly above neutral on several measures of SWB, a very small minority reported perfect LS, or *always* experiencing pleasant affect (Biswas-Diener et al., 2005). Thus, the skew in well-being seems to reflect a moderate form of happiness. Although measurement artifacts are an important concern (see "Methodological Issues"), the replicability of these findings across numerous societies and over a number of different methods is impressive.

Perhaps it should not seem so shocking that most people are at least mildly happy with their lives. Some researchers argue that a disposition toward pleasant affect facilitates exploratory behavior, which could have conferred evolutionary advantages (E. Diener & Diener, 1996; Fredrickson, 1998; Ito & Cacioppo, 1999). According to Ito and Cacioppo, the motivational system is slightly biased toward approach behavior, even in the absence of stimuli—a phenomenon called "positivity offset." Such a bias would be more advantageous than a purely neutral disposition, because, in the absence of danger, it would help humans learn more about their environment. As a consequence of broadening behavioral and attentional foci, positive emotions might also have helped humans to build social relationships and other resources important for survival (Fredrickson, 1998). The connection between pleasant affect and approach tendencies receives some support from a 27-nation study by Wallbott and Scherer (1988). With few cultural differences, participants reported that "moving toward" was an action tendency most characteristic of joy, whereas "withdrawing" was more typical of unpleasant emotions.

In light of this research, it becomes important to ask when and why a society falls below the midpoint of SWB. One observed trend is that people living in severe destitution often report being unhappy. Prostitutes and homeless people living in Calcutta, India, reported negative levels of LS (Biswas-Diener & Diener, 2001). The LS of Malaysian farmers living below the poverty line also fell below the midpoint (Howell, Howell, & Schwabe, 2006). Difficulty in meeting basic needs or other circumstances, such as lack of respect, might have decreased the well-being of these groups. In the

next section, we consider how economic factors might influence the SWB of a society.

Economic Development and Related Variables

The wealth of a nation frequently correlates with its level of SWB. Depending on whether one looks at purchasing power or per capita gross domestic product (GDP), the correlation between economic wealth and the SWB of a nation ranges from .58 to .84 (E. Diener, Diener, & Diener, 1995; Inglehart & Klingemann, 2000; Veenhoven, 1991). As robust as this finding is, the exact process by which economic development increases happiness remains unclear.

Wealthier societies are better able to meet the basic needs of their citizens, and this contributes to SWB (E. Diener, Diener, et al., 1995). We consider the role of basic needs fulfillment in a later section. For now, it is also worth noting that economic development is often associated with many other social conditions. For example, wealth correlates with greater human rights, as well as greater equality (in income, access to education, and between the sexes; E. Diener, Diener, et al., 1995). Rights and equality also correlate with each other. Moreover, people in wealthier nations are often more satisfied with friends and home life (E. Diener & Suh, 1999). A possible explanation proposed by Ahuvia (2002) is that rising wealth alters the cultural environment by freeing the individual from economic dependence on his or her family. This independence could attenuate norms for reciprocity while facilitating the pursuit of individual happiness (e.g., by allowing one more choice in friends and lifestyle). Thus, several mechanisms are possible, and the various correlates of wealth make it difficult to isolate the unique contribution of wealth to SWB. The relation between economic development and SWB is thus entangled in a causal web of several factors, and future researchers need to separate their causal influences on SWB.

Aside from economic development, Inglehart and Klingemann (2000) suggested that national levels of SWB might also reflect historical factors. In 1997, the former communist states of Eastern Europe and the U.S.S.R. had among the lowest levels of well-being—lower than nations with less wealth, but without a history of communism. Even after controlling for wealth, rights, and other variables, the number of years under communist rule nega-

tively predicted a nation's mean level of SWB. However, Inglehart and Klingemann warn against hasty praise for capitalistic or democratic societies. Although the collapse of communism in the Soviet Union was preceded by relatively low levels of SWB, it was followed by *even lower* levels of SWB (see also Veenhoven, 2001). Political instability and economic decline after the fall of communism may have created conditions inimical to SWB. These ideas require further research, especially as conditions change in the region.

Norms for Emotions

As mentioned earlier, the experience of well-being can be shaped by cultural norms regarding the desirability of LS or certain emotions (M. L. Diener et al., 2004; Suh et al., 1998). Desirable emotions might be experienced more frequently than those that are seen as inappropriate (M. L. Diener et al., 2004) or they may correlate more with general happiness (Markus & Kitayama, 1994). Norms for emotions may explain why Asian—especially East Asian—samples often report lower SWB than those from Europe and the Americas (E. Diener & Diener, 1995; Kang, Shaver, Sue, Min, & Jing, 2003; Sheldon et al., 2004; Suh, 2002). Economic development may be a factor, but it cannot completely account for the lower SWB of East Asians. For example, Japan has greater purchasing power than many Latin American nations (E. Diener, Diener, et al., 1995), yet it reports lower SWB than do the latter (E. Diener & Suh, 1999; E. Diener & Oishi, 2000). This could be because Japanese and other Asians show a greater acceptance of unpleasant emotions than do people in the Americas (E. Diener & Suh, 1999). Moreover, East Asians may also value low activation positive affect (e.g., serenity) more than high activation positive affect (e.g., excitement) because the former emotions facilitate collectivist goals of attending to the social context (Tsai et al., 2006).

How might emotion norms translate into experience? One pathway is through the socialization of emotions in children (M. L. Diener & Lucas, 2004) and the willingness to report specific emotions, or through recall of which emotions are experienced (Oishi, 2002). Wirtz (2004) asked participants to report how they felt about past events, both currently and at the time of the event. Whether the emotions were pleasant or unpleasant, Japanese participants'

current feelings were less intense than their remembered feelings from the past. In contrast, European Americans reported significant decay for unpleasant but not pleasant emotions. Thus, cultural norms might also shape the relation between recalled emotions and current feelings, which might also influence judgments about current LS.

Schimmack, Oishi, and Diener (2002) suggested that East Asian views of pleasant and unpleasant emotions might be rooted in the dialecticism of Asian philosophies (e.g., Buddhism and Daoism) that have historically shaped these cultures. For example, in Chinese folk wisdom, both sides of a contradiction are equally likely, and a compromise between the two is preferable (Peng & Nisbett, 1999). East Asian emotion norms may be dialectical in the sense that a middle way between extreme pleasant and extreme unpleasant affect is considered desirable. In contrast, many Western European and Latin American cultures prefer pleasant over unpleasant affect. These cultural differences are reflected in emotion reports. Among participants from Western Europe and the Americas, the frequency of pleasant affect was inversely related to the frequency of unpleasant affect (Schimmack et al., 2002). Among Asian participants, however, this negative correlation was weak (see also Bagozzi, Wong, & Yi, 1999). Kitayama, Markus, and Kurokawa (2000) actually observed a *positive* correlation between pleasant and unpleasant affect in Japan. Finally, over a 1-week period of experience sampling, Scollon et al. (2004) found that European Americans and Hispanic Americans experienced more pleasant affect than Asians and Asian Americans. Moreover, there were no differences in unpleasant emotions. Asians and Asian Americans did not experience as much pleasant affect as the other groups, but they were not biased in the direction of greater unpleasant affect either.

Are East Asians simply unhappy at worst and apathetic at best? Caution must be taken not to equate lower levels of well-being as *ill-being*. First, the SWB of East Asians is lower *in comparison to* Latin Americans and Western Europeans. Although mean levels of SWB are often lower among Asian samples, they are rarely below the neutral midpoint. Second, Kitayama and Markus (2000) note that balance and moderation are central to East Asian concepts of health. A preference for low- rather than high-activation positive affect may be

consistent with this perspective (Tsai et al., 2006).

Another source of cultural variation in emotion norms may be religious doctrine. Across 40 nations, Kim-Prieto and Diener (2004) found that Christians reported a greater frequency of happiness and less shame than Muslims, even after controlling for the effect of nations. A subsequent comparison of the emotion content of religious texts revealed that joy and love were more frequently mentioned in the New Testament, whereas shame and guilt were more frequently mentioned in the Quran. Thus, differences in norms or the socialization of emotions may be rooted in religious doctrine. An important implication of these findings is that the cultural forces that impinge on SWB may extend beyond ethnic and geographic delineations.

Genetic Differences

Might cultural differences in well-being be due to genetic differences between groups? Although much more research is needed, some individual differences in SWB may be related to genetics. Polymorphisms in the serotonin-related *5-HTT* gene have been linked to individual differences in anxiety (Lesch et al., 1996), as well as susceptibility to depression (Caspi et al., 2003). Lykken and Tellegen (1996) maintain that roughly half of the individual variance in SWB is related to genetic variation.

A limitation of this research is that it has been carried out within single societies, and effects *within* a sample may not necessarily be driven by the same causal forces as those *between* samples. Although there are ethnic and cultural differences in gene frequencies (Cavalli-Sforza, 1991), direct links between such differences and SWB have not yet been made. However, studies of infant temperament reinforce the possibility of genetic effects. Freedman and Freedman (1969) found ethnic differences in infants less than 4 days old. Compared to European American infants, Chinese American infants were calmer and less reactive to a cloth placed on their face. Similarly, 4-month-old infants in China exhibited less behavioral arousal than did European American and Irish infants (Kagan et al., 1994). Nevertheless, the role of socialization practices cannot be overlooked. In contrast to these findings, Ahadi, Rothbart, and

Ye (1993) found that 6-year-old Chinese children exhibited relatively more negative affectivity than did their European American peers. The authors suggested that strict Chinese socialization practices might foster a greater sensitivity to punishment, leading to more frequent negative affect. Thus, genetic influences do not rule out the impact of life circumstances on the various components of SWB. Recently, Diener and colleagues (E. Diener, Lucas, & Scollon, 2006; Fujita & Diener, 2005) argued for a “soft set point” conception of SWB. People can adapt to many situations, and genes may account for some of the stability in SWB. However, life events and social conditions (e.g., widowhood or poverty) can still have a substantial impact on happiness at both individual and group levels. Much more research on culture, genetics, and SWB is required before firm conclusions can be made.

Conclusion

In many societies, a majority of the people report being happy, but very few report extreme happiness. Although there are biological and evolutionary accounts for why this is so, other factors are likely to influence mean levels of well-being. These factors include economic development and cultural norms for emotions. However, much more research is needed before we can understand exactly how and why societal levels of SWB differ across cultures. Specifically, the exact process underlying the relation between economic development and SWB remains unclear, as does how such development affects cultural values related to well-being.

CORRELATES AND CAUSES OF SWB

Cultures might differ in not only the type and frequency of emotions people experience but also in the causes of SWB. Often the evidence is in terms of cross-sectional correlations, however, so we mostly review what covaries with pleasant and unpleasant affect, and LS in different cultures. Furthermore, Kitayama and Markus (2000) suggested that SWB is not only personal happiness but also includes one's relations with others. Thus, happiness might take different forms across cultures, with different factors causing it.

The Self and SWB

To the extent that self-concepts vary across cultures (Markus & Kitayama, 1991), one might expect the relation between self and SWB to vary as well. For instance, although self-esteem is often a strong correlate of LS, Heine et al. (1999) questioned the need for positive self-views in collectivist cultures. In Japan, where interdependence is emphasized, a self-critical tendency may be valued as a way of improving one's ability to meet social obligations (but see Brown & Kobayashi [2002, 2003] for evidence of self-enhancement in Japan, and Heine's [2003] response). Miller, Wang, Sandel, and Cho (2002) found that rural Taiwanese mothers also place little emphasis on developing their children's self-esteem, and some worried that high self-esteem would impair their child's capacity to take criticism. Thus, in collectivist cultures, self-esteem may be viewed as unimportant, or even *undesirable*, for achieving cultural goals. In contrast, a primary concern for European American mothers was to help their children develop and maintain a strong sense of self-esteem (Miller et al., 2002).

If high self-esteem is deemphasized in collectivist cultures, then one might expect self-esteem to relate less strongly to LS than it would in more individualist cultures. This is exactly what a number of researchers have found (E. Diener & Diener, 1995; Oishi, Diener, Lucas, & Suh, 1999; Park & Huebner, 2005). Although self-esteem correlated with LS across most countries, the strength of association could be predicted by the individualism of a country. For example, self-esteem and LS correlated .60 in the United States, but only .08 among women in more collectivist India (E. Diener & Diener, 1995). Similarly, Park and Huebner (2005) found that satisfaction with self was a much stronger predictor of LS for U.S. adolescents than for Korean adolescents. As with emotions (Suh et al., 1998), people in collectivist cultures may be guided by norms downplaying the importance of self-esteem when they make LS judgments. Alternatively, people with high self-esteem may be frowned upon in collectivist cultures for holding or expressing attitudes that violate norms. Of course, norms should also influence the factors that *do* correlate with LS. For example, Park and Huebner (2005) suggested that the heavy emphasis on academic achievement in Korea might explain why school satisfaction pre-

dicted LS for Korean adolescents but not for American adolescents.

Another characteristic that may be less socially valued in collectivist cultures and less important for SWB is identity consistency. In traditional Western psychology, self-consistency across situations implies a coherent self-identity and good mental health. However, in East Asian cultures, where individuals are expected to adjust themselves to the social situation, identity consistency might be taken as a sign of immaturity. Suh (2002) found that Americans evinced greater consistency than Koreans across social roles. For example, if Americans were talkative with their friends, they were also more likely to be talkative with parents, siblings, and strangers than were Koreans. Furthermore, identity consistency was a much stronger predictor of SWB for Americans than for Koreans. Not only were self-consistent individuals happier in the American sample, but they were also rated by informants as more likable and socially skilled than less consistent individuals. In contrast, Korean informants showed no such preference for consistent targets (Suh, 2002).

Culture may also affect the relation between personality and LS. On the one hand, research suggests that the influence of personality on emotional experience may be pancultural (Lucas, Diener, Grob, Suh, & Shao, 2000; Tsai et al., 2006). In five countries, Schimmack et al. (2002) found that extraversion correlated positively with affect balance, whereas neuroticism was negatively correlated. Moreover, the relation between personality and LS was mediated by affect balance. Thus, extraverts enjoy greater LS in part because they experience frequent pleasant affect. However, because the relation between *emotions* and LS is stronger in individualist cultures (see "Patterning and Structure"), the relation between personality and LS is also moderated by culture. Thus, extraversion and neuroticism are more predictive of LS in individualist cultures (Germany and the United States) than in collectivist cultures (Ghana, Japan, and Mexico). Extraverts everywhere may experience more pleasant affect than neurotics, but how much this contributes to LS may depend on the cultural value of emotional experience. Alternatively, Benet-Martínez and Karakitapoglu-Aygun (2003) proposed that cultures favor the development of some personality traits over others. They found that individualism predicted both

extraversion and neuroticism, and that the relationship between personality and LS was mediated by self-esteem and friendship satisfaction.

An important issue concerns the role of autonomy in SWB. Self-determination theory (SDT; Deci & Ryan, 1985; Ryan & Deci, 2000) contends that autonomy is a basic human need that, if not fulfilled, will lead to lower levels of well-being. One source of the debate may be the very definition of autonomy. For example, Oishi (2000) operationalized autonomy as horizontal individualism (i.e., an emphasis on independence and individual self-worth). He found that the positive association between autonomy and LS is stronger in more individualist nations such as Australia and Denmark, than in more collectivist nations such as China, Korea, and Bahrain. However, Chirkov, Ryan, Kim, and Kaplan (2003) argued that the construct of autonomy must be distinguished from independence and individualism (see also Ryan & Deci, 2000). In the framework of SDT, autonomy is the sense that one has willingly engaged in and fully endorses an act. Individuals may be dependent on others and still experience autonomy, if they find value in that dependence and engage in it of their own volition. What is of importance is the *internalization* of the values that one is exercising. Thus, although Koreans viewed their culture as more collectivist and less individualist than Americans viewed their own culture, the internalization of *both* types of values predicted SWB in both countries, as well as in Russia and Turkey (Chirkov et al., 2003). Using a similar definition of autonomy, Sheldon et al. (2004) found that self-concordant individuals (i.e., those who pursued goals they perceived as freely chosen) tend to report higher levels of SWB in the United States, South Korea, Taiwan, and China. Thus, autonomy as independence is not universal, whereas autonomy as feeling that one's behavior is freely chosen and not coerced may be universal.

These views are not contrary to the goal-as-moderator model advanced by Oishi (2000). This model posits that the relation between culture and SWB is moderated by personal goals. Culture may influence one's goals, but individuals do not always pursue culturally endorsed goals. For example, a Chinese student who values personal success may be happier studying alone than offering help to his fellow classmates, although the latter better reflects the

cultural goal of interdependence. However, although attaining personal goals may bring emotional well-being, it may not always yield a sense of meaning in life. Ideally, personal goals that are aligned with cultural values lead to both happiness and meaning (Oishi, 2000). Thus, the role of personal goals is similar to the importance of internalization proposed by SDT. Although independence from others might not predict happiness equally across cultures, acting from one's volition is predicted by both SDT and Oishi's theory to lead to happiness universally.

Both perspectives suggest that the distinction between personal and collective goals may often be blurred. For example, the SWB of Asians and Asian Americans is better predicted by satisfaction with goals involving family and friends than with goals concerned mainly with the self (Oishi & Diener, 2001; Radhakrishnan & Chan, 1997). However, among collectivist cultures, the goals of one's group may also be experienced as one's own (Markus & Kitayama, 1994), making them both collective and personal. In contrast, only personal goals were predictive of the SWB of European Americans (Oishi & Diener, 2001; Radhakrishnan & Chan, 1997). Taken together, the findings suggest that some motives may correlate universally with well-being, whereas other motives or goals are culture-specific correlates of well-being.

Relationships with Others and SWB

The preceding research implies that social relationships may influence SWB differently across cultures. For instance, although emotional experience is often considered private and internal, Kitayama and Markus (2000) suggested that the Japanese may experience good feelings *intersubjectively*, as features of an interpersonal situation that dissipate once the individual is out of that context. Consistent with this idea, Oishi, Diener, Scollon, and Biswas-Diener (2003) found that Japanese reported less pleasant affect when alone than did Americans. Furthermore, although both groups experienced more pleasant affect when with friends than when alone, the effect was greater for the Japanese (as well as for Hispanic Americans; Oishi et al., 2003).

In general, East Asians may be more other-focused in their emotional experience than North Americans (Cohen & Gunz, 2002;

Kitayama et al., 2000). Kitayama et al. compared how *engaged* (relationship focused) and *disengaged* (self-focused) emotions relate to general good feelings (e.g., happiness) among Japanese and American participants. For Japanese participants, positive engaged emotions (e.g., friendly feelings) correlated more strongly with general good feelings than did positive disengaged emotions (e.g., pride). The reverse was true for American participants. However, a recent priming study by No and Hong (2004) suggests that the influence of culture on emotional experience is dynamic. Compared to baseline, Korean American biculturals primed with Korean cultural icons became more relational and less egocentric in their projection of emotions onto others. Similar effects may be observed in the experience of SWB; that is, what makes an individual happy may shift as the salience of cultural frames shifts, such as when living in another culture for an extended period of time.

The relative importance of relationships across cultures also influences LS. Among Hong Kong Chinese, for example, relationship harmony was just as important as self-esteem in predicting LS (Kwan, Bond, & Singelis, 1997). In contrast, self-esteem was a stronger predictor of LS for Americans. Interestingly, relationship quality may have both direct and indirect effects on LS. Kang et al. (2003) not only replicated Kwan et al.'s (1997) findings in the United States, Korea, and mainland China, but they also showed that relationship quality was positively associated with self-esteem in the latter two groups. Relationship quality was also predictive of Asian Americans' self-esteem, but *not* of European Americans' self-esteem (Kang et al., 2003).

A relationship of particular relevance to SWB is marriage. Across 42 societies, married people reported more pleasant and less unpleasant affect than the divorced (E. Diener, Gohm, Suh, & Oishi, 2000). However, small cultural effects were observed. Divorce seems to reduce pleasant affect to a lesser extent in collectivist than in individualist cultures. Gohm, Oishi, Darlington, and Diener (1998) found that in collectivist cultures, the offspring of divorced parents reported greater LS than those whose parents remained in high-conflict marriages. These groups did not differ in individualist cultures. Both findings could be related to greater social support in collectivist cultures, which would help to sustain well-be-

ing after divorce. Alternatively, the pressure to stay together may be greater in these societies, so that couples divorce only after severe marital conflict. In this case, the decision to divorce might offer greater relief to spouses and their offspring. More research is needed to test these hypotheses.

Income and SWB

According to Veenhoven (1991), income contributes to SWB only insofar as it allows one to fulfill basic needs. Beyond the level needed to satisfy physical needs, income has less of an impact on SWB. Veenhoven's theory resembles that of Maslow (1954), which posits that lower-order needs (e.g., physical and security needs) must be gratified before higher-order needs (i.e., belongingness, esteem, and self-actualization) become salient. However, some scholars have questioned whether the fulfillment of needs follows a linear hierarchy (Yang, 2003). Moreover, diminishing returns on the effects of material goods do not always imply that higher-order needs have been prioritized. An implication drawn from both theories, however, is that income has a greater impact on SWB in poor societies, because physical needs such as having adequate food, water, and housing are highly salient, and the effects of income on meeting these needs are direct. Indeed, researchers have found that financial satisfaction predicts LS more strongly in poorer than in wealthier countries (E. Diener & Diener, 1995; Oishi et al., 1999).

Although the relation between income and happiness is reduced among the wealthier nations, it is worth noting that income still contributes to SWB *beyond* the basic subsistence level (Diener, Diener, et al., 1995; E. Diener, Sandvik, Seidlitz, & Diener, 1993). Perhaps greater amounts of income facilitate the pursuit of other goals (e.g., relationships or philanthropy) that add to one's level of SWB, though little is known about *how* money is spent across cultures.

Although Maslow's needs hierarchy provides some understanding of the link between income and SWB, it is important to consider recent revisions of and critiques on the cross-cultural applicability of this model. Yang (2003) argued that Maslow's higher-order needs (belongingness, esteem, and self-actualization) are framed within an individualist context. He suggested that in collectivist

societies, these needs are framed in ways that reaffirm social relationships and group identity. Moreover, he proposed (after Yu, 1992, cited in Yang, 2003) that bearing and rearing children be considered needs that are present in all societies, because they ensure the transmission of genes to the next generation. Unlike the strictly hierarchical nature of Maslow's model, Yang suggested that needs can be experienced and fulfilled simultaneously. For example, raising children may fulfill both belongingness and esteem needs. Furthermore, individuals may emphasize or deemphasize transmission needs throughout the life course. The relative importance of child-rearing versus esteem needs might also differ across cultures, and the role that income plays in satisfying these needs could likewise vary.

Conclusion

A number of correlates of SWB are strikingly different across cultures, yet some correlates appear to be universal. Variations in the cognitive and affective experience of happiness correspond with cultural differences in self-definition and the importance of social relationships. Income also contributes to SWB, though the relation is stronger among poorer than among wealthier societies. Thus, cultural-psychological differences are rooted not only in values but also in the material world. However, because culture is dynamic, what makes people happy may change across generations, as well as within the individual, as different aspects of a culture become salient. Nevertheless, there may be some universal correlates of SWB even in the face of cultural variations, such as autonomous internalization of cultural values.

OUTCOMES OF SWB

Research on SWB has traditionally been a search for the who, what, and how of happiness—that is, who is happy, what makes people happy, and how the various components of happiness relate to each other. Because happiness has historically been thought of as an end in itself, these were the first questions to be asked, and the field of SWB advanced greatly as these issues began to be studied more rigorously. However, the question of *why* happiness is important has only recently received more serious attention.

Lyubomirsky, King, and Diener (2005) propose that although success may produce happiness, it may also be the case that happiness leads to success. They reviewed several experimental and longitudinal studies suggesting that many outcomes of pleasant affect are desirable (e.g., prosocial behavior, self-esteem, likability, creativity, and longevity). These characteristics in turn lead to success in many life domains, such as marriage, work, and health. The framework developed by Lyubomirsky et al. is an intriguing area that requires much more research. Not only does the direction of causality await further clarification in some domains but also the benefits and *costs* of pleasant affect must be investigated in a wider range of cultures.

The studies reviewed by Lyubomirsky et al. (2005) were conducted primarily in North America, Europe, and Australia. Whether pleasant affect is similarly beneficial in, for example, East Asia is certainly open for analyses. Would pleasant emotions produce similar outcomes in Japan, where self-criticism and self-improvement are seen as important for success (Heine et al., 1999)? Heine et al. (2001) observed that North Americans are more likely to persist on a task after receiving success feedback, whereas Japanese are motivated to persist if they receive failure feedback. The facilitative effect of pleasant affect among Westerners may be related to the general desirability of these emotions in their cultures (Eid & Diener, 2001). However, East Asian cultures do not devalue all pleasant emotions (e.g., Tsai et al., 2006). An important topic for future investigation is whether specific pleasant emotions are beneficial, whereas others (e.g., pride; Eid & Diener, 2001; Scollon et al., 2004) are detrimental for success in certain cultures.

At a societal level, Inglehart and Klingemann (2000) suggested that rising levels of SWB might help legitimize and stabilize newly formed governments. They pointed out that major political changes in Belgium and the former U.S.S.R. in the early 1990s were *preceded* by decreasing levels of SWB. Furthermore, although many democratic societies had high levels of well-being, democracy did not predict SWB after controlling for gross national product (GNP; Inglehart & Klingemann, 2000). Thus democratic institutions may increase SWB through rising wealth, but greater SWB might also help to sustain these institutions. These propositions are preliminary, and more research is required to understand the causal

process. Measuring national levels of SWB consistently and over a broad period of time could shed light on how fluctuations in well-being relate to sociopolitical developments.

METHODOLOGICAL ISSUES

A critical question is whether measures of SWB are valid and reliable across cultures. Even within cultures, Schwarz and Strack (1999) pointed out several potential threats to the validity of self-reported SWB. They warned that self-reports are vulnerable to contextual factors (e.g., question wording and order effects) that can change the standards by which people evaluate their lives. However, Schimmack, Diener, and Oishi (2002; Oishi, Schimmack, & Colcombe, 2003) showed that the information people use to make LS judgments is largely systematic and personally relevant. Thus, although self-reports of SWB may be subject to momentary influences, more often than not, they convey meaningful information about an individual's evaluation of his or her life.

Nevertheless, there are additional challenges when SWB research is conducted across cultures. A basic issue is the adequate translation of written materials. Poor translations can alter the intended meaning of SWB measures, leading to spurious cultural differences. A number of studies, however, suggest that translation effects are unlikely to explain the substantial cultural differences that have been observed. For example, bilingual Chinese reported lower life satisfaction than bilingual European Americans, whether they completed the SWLS in Chinese or in English (Shao, 1993). Similarly, M. L. Diener et al. (2004) gathered reports of emotional experience from multiple locations in China, Singapore, and India. Within the same country, some subsamples completed the survey in the local language, whereas others completed an English version. Results indicated that subsamples *within* a nation were more similar in emotional experience, regardless of the language used. Cultural differences obtained with translated measures of SWB have also been substantiated by *non*-self-report measures (Balatsky & Diener, 1993; Biswas-Diener et al., 2005). For instance, not only did Russians report lower SWB than Americans, they also recalled proportionately less positive events than did the latter (Balatsky & Diener, 1993).

Another issue is whether the use of numbers, or unfamiliarity with Likert scales could affect findings. In the slums of Calcutta, Biswas-Diener and Diener (2001) supplemented their 7-point Likert scales with a gradient of frowning and smiling faces. Some respondents were still confused by the task, forcing the researchers to reduce their measures to a 3-point scale. Despite these initial difficulties, they obtained an alpha coefficient of .80 for the SWLS. Still, when conducting research in certain cultures, the novelty of psychological testing can result in lower reliabilities (e.g., Biswas-Diener et al., 2005). Moreover, the reliability of the SWLS was found to correlate positively with the GNP of a nation (Vittersø et al., 2002). Higher reliabilities do not completely account for the greater LS found in wealthier nations, but they do appear to influence results and may be due to greater familiarity with psychological testing in those countries. Nevertheless, measures of LS and happiness are predictive of social integration and elderly suicide rates across nations (Wu & Bond, 2006), providing some evidence that these measures are capturing important aspects of people's life experiences.

Different response styles have occasionally been proposed as an explanation for cultural differences in well-being, especially with regard to the lower SWB among Asian samples. One hypothesis is that due to humility norms, Asian respondents tend toward neutrality by overselecting responses at the midpoint of the scale. E. Diener, Suh, Smith, and Shao (1995) examined this possibility among Chinese, Japanese, Korean, and American samples but did not find such a tendency. East Asians showed as much variation as Americans in their satisfaction with various domains. The former even reported a greater range of emotional intensity than the latter. Similarly, Veenhoven (2001) showed that negative response tendencies are unlikely to explain the lower levels of SWB among Russians. Interestingly, the lower scores on SWB run counter to the finding that acquiescence bias (the tendency to respond in agreement with items) tends to be higher in collectivistic nations (Johnson, Kulesa, Cho, & Shavitt, 2005; Smith, 2004). If acquiescence influences responses on SWB measures, one would expect to see higher means in East Asia, but this is clearly not the case.

On the other hand, social desirability may underlie some differences in reported SWB. In

cultures where LS and pleasant affect are considered desirable, there may be a tendency to project higher SWB. People in some cultures appear to have a “positivity bias,” in which satisfaction with global domains (e.g., education) are high even though satisfaction with more specific domains (e.g., textbooks, professors, and lectures) are *lower* on average (E. Diener, Scollon, Oishi, Dzokoto, & Suh, 2000). E. Diener, Scollon, et al. found that this positivity bias predicted LS beyond objective measures such as income, and that it correlated positively with norms for LS. This finding may explain the discrepant relation between wealth and happiness in Japan and Latin America. Latin Americans exhibited high desirability for LS, as well as a strong positivity bias. In contrast, Japanese and other East Asians reported lower desirability for LS and a corresponding *negativity* bias, such that global satisfaction was lower than would be expected from specific domain satisfactions (E. Diener, Scollon, et al., 2000). These biases could be considered artifacts, but they may also represent interesting cultural phenomena in and of themselves. Furthermore, it is worth reiterating that cultural differences in satisfaction judgments and emotional experience have been observed using other methodologies. For instance, a 1-week daily diary study showed that European Americans’ global past-week satisfaction was more positive than their average satisfaction for *each day* of that week (Oishi, 2002). In contrast, Asian American participants did not exhibit a significant bias in global versus daily satisfaction ratings. Similarly, Kim-Prieto (2005) found that European Americans and Asians were similar in happiness reported “now,” but Asians reporting feeling less during the past year and “in general.” Finally, the recall of *pleasant*, but not unpleasant emotions during a vacation predicted the desire of European Americans to repeat the trip, whereas for Asian Americans the reverse was true (Wirtz, 2004). Interestingly, experience-sampling data revealed that the two groups did not differ in their *online* experience of pleasant and unpleasant emotions. Thus, the global judgment, and not the specific reports, influenced participants’ decisions. Instead of dismissing global judgments altogether, E. Diener, Scollon, et al. (2000) suggested that global and domain-specific judgments are both distinctly informative aspects of SWB. Nevertheless, cross-cultural researchers should continue to use

multiple methods (memory measures, informant reports, etc.) whenever possible.

Perhaps a fundamental concern is whether it is appropriate to use nations as a proxy for studying culture. Researchers often define groups by their countries of origin and attribute any differences among these groups to culture. However, culture is not necessarily confined to geopolitical boundaries (Hermans & Kempen, 1998; Hong & Chiu, 2001). By equating entire nations with single cultures, we risk overlooking important differences within nations, as well as similarities that extend beyond national borders. In the case of emotion norms, many different norm patterns for pleasant and unpleasant affect may coexist within a nation (Eid & Diener, 2001). At the same time, however, nations within a certain *region* (e.g., East Asia or Latin America) appear to have similar patterns of emotional experience (M. L. Diener et al., 2004).

It is not entirely meaningless to group samples by nation. People living within a country are likely to have shared experiences and common histories, which are crucial in the formation of a common culture. Still, cultural entities may be defined at different levels, in any number of ways. It is important to realize the trade-offs inherent at a given level of analysis. Speaking of “regional cultures” allows us to make generalizations, but at the sacrifice of specificity. A focus on subcultural grouping may provide rich, nuanced data, but at the cost of generalizability. A further point is that culture is dynamic. The penetration of Western media and popular culture into other parts of the world can stimulate cultural change, leading to generational differences within nations. Thus, different age groups within a nation might differ in their attitudes and experience of SWB. More longitudinal research is needed to disentangle cohort effects from developmental effects.

Finally, group differences in SWB might be related to socioeconomic status (SES), not just to cultural beliefs and values per se. Income and education levels can determine the quality of life for people in a society, which in turn could lower or raise SWB. However, SES may sometimes be confounded with cultural groupings, especially when a history of discrimination has prevented certain groups from attaining higher status (Betancourt & López, 1993). Apart from discrimination, people from high versus low SES groups may face different reali-

ties and prioritize different values and beliefs (e.g., Snibbe & Markus, 2005). In either case, controlling for SES would result in a removal of cultural effects as well. Thus, separating SES from culture may not always be a straightforward task. On the other hand, cultural effects that persist even after controlling for socioeconomic variables pose interesting questions for future research and theory (see Rice & Steele, 2004) concerning the nature of culture and how it should be operationalized.

FUTURE DIRECTIONS

Although cultural variations in SWB have been replicated across self-report and memory measures, an important agenda for future research is to determine the extent to which these differences are reflected in the actual experience of well-being. More frequent applications of the experience-sampling method across cultures will provide further clarification of such differences. In one of the few such studies, Scollon et al. (2004) found that cultural differences in reports of past emotional experience do have some basis in online experience, but they also reflect aspects of the self-concept that independently influence the recall of emotions. These findings are provocative, but they must be replicated across more cultures. Other methods of assessing SWB, such as Kim's (2004) implicit association measure of LS, have only recently been developed and could provide further insights. Also critical will be the further development and integration of biological markers of well-being. For example, a predisposition toward positive affectivity has been linked to individual differences in chronic left-brain activation (Ito & Cacioppo, 1999). The immune system and neurotransmitter systems (e.g., serotonin and dopamine) may also play a role in well-being. These and other types of measures will help us know whether differences in SWB lie in actual experience or only in self-reports.

There is also a continuing need for theory on the functioning of SWB in culture—how it is defined in each culture, how it supports culture, and the types of outcomes associated with SWB in various societies. SWB is an important criterion for evaluating the success of a society, but by itself it is insufficient. To be happy in the face of starvation or inequality would seem preposterous to most people. Happiness and cultural conceptions of the good life are often

tied to the sociomoral fabric of a society. As Markus and Kitayama (1994) suggested, being a competent member of one's culture typically "feels good" or "right." Thus, in some ways, LS may involve an implicit moral judgment on one's life, or on oneself as a person. Future studies of indigenous concepts of well-being, as well as the relation of SWB to the moral structures of a society, will help researchers further contextualize their interpretations of SWB.

Finally, viewing culture dynamically will enhance our understanding of cultural variation in SWB. Dynamic constructionists (e.g., Hong & Chiu, 2001) suggest that the influence of culture is not rigid and sweeping, but that it can fluctuate with the social context. Particularly among immigrants and other individuals who have been exposed to multiple cultures, *which* culture is influential may depend on cues in the environment (e.g., at home vs. at school) that activate different sets of cultural knowledge. An intriguing issue is how such cultural frame switching might moderate the relation between LS and correlates such as self-esteem. How bicultural individuals feel about and integrate their cultural identities (Haritatos & Benet-Martínez, 2002; Kim, Sarason, & Sarason, 2006) might also influence their well-being as they navigate between different cultural contexts. A related topic is how the causes of SWB change across the lifespan, or across different cohorts within the same culture. Thus, dynamic cultural perspectives contribute to a more fluid notion of SWB, raising new questions about the structure of well-being and its outcomes.

CONCLUSIONS

We have learned that comparisons of well-being are possible for some variables, and that there are probably some universal causes of well-being and ill-being. At the same time, we have learned that fascinating differences exist between cultures in the patterning and content of SWB variables, as well as in the causes and correlates of SWB. These differences should guide us in our attempts to make valid comparisons. For instance, some emotions may be understood similarly across cultures, whereas others have different connotative meanings. Direct comparisons, then, should be made with the former and not the latter. Even where SWB components are different, we could compare

cultures according to their own criteria by measuring the attainment of culturally valued goals and experiences. Such an approach to well-being still allows us to assess success in different cultural contexts.

The effect size of culture on well-being can vary depending on the specific component of SWB under study. Cultures perhaps vary more in frequency and perceived norms for pleasant emotions than for unpleasant emotions (Eid & Diener, 2001; Scollon et al., 2004). In the case of unpleasant emotions, there is a stronger trend toward much larger differences within than between cultures. The uneven effects of culture on SWB not only resonate with dynamic views of culture but also call for circumspection in the type of inferences we draw from societal levels of SWB.

Much has been learned in the past decade of research in culture and SWB. Researchers began by making simple comparisons of nations on life satisfaction and happiness. Next they began to ask questions about the validity of measures across cultures, and about the causes and correlates of SWB in different societies. The field continues to advance, with more sharply focused research questions concerning *when* cultural influences come into play, *which* aspects of well-being are affected, and *what* the outcomes of SWB are across cultures. We are also entering an era in which research will treat culture as more dynamic, and individuals as bearers of more than one cultural tradition. These issues will continue to require multi-measure strategies and, we hope, stimulate the development of new methodologies. In this regard, progress in the various areas of cultural psychology and SWB, as well as more interdisciplinary work with the other social and biological sciences, will benefit both perspectives greatly.

ACKNOWLEDGMENTS

We would like to thank Sumie Okazaki for her helpful and insightful comments on an earlier draft of this chapter. This work was supported by a National Science Foundation Graduate Fellowship awarded to William Tov.

NOTE

1. The Oriya emotion *lajya* or *lajja* was translated by Menon and Shweder (1994) as shame. However, a less

negative, alternative translation is “feeling shy.” These two emotions are related but not the same. We thank Vijay Kumar Shrotriyia for this observation. Our point is simply that the meaning of an emotion (hence, its value) can shift in different cultural contexts in ways that are not obvious from its valence alone.

CHAPTER 29

Culture and Motivation

What Motivates People to Act in the Ways That They Do?

STEVEN J. HEINE

What motivates people to act in the ways that they do? It is difficult to conceive of a more fundamental question in psychology. Many key social-psychological theories regarding topics such as cognitive dissonance, conformity, agency, approach–avoidance, self-enhancement, and achievement are grounded in an understanding of the forces that impel human behavior.

Although questions regarding motivation have been central to psychology since the earliest days of the field, not until recently was focused consideration directed at the ways that culture might be implicated in human motivations. On the one hand, it is not obvious that people from divergent cultures would be motivated differently. After all, humans are all of the same species, and we should expect a great deal of similarity in their motivations, regardless of cultural background. Indeed, a variety of key psychological motivations are likely common across all human cultures. For example, people everywhere want things that improve the quality of their lives, such as getting access to nice material rewards, having stimu-

lating relationships, and earning the respect of their peers (for a review, see Kenrick, Li, & Butner, 2003).

On the other hand, humans are unlike all other species in the extent to which they depend on cultural learning to survive (e.g., Tomasello, 1999). Because of this, human motivations cannot be understood solely in terms of biological predispositions interacting with the constraints and affordances provided by physical environments. Rather, those biological predispositions are expressed in the context of particular cultural environments that shape the ways motivations are made manifest. For example, the ways that people get access to material rewards, the kinds of relationships that they might find stimulating, and the ways they secure the respect of their peers are not identical across all contexts. They are rooted in people's values, their beliefs about what can be easily accomplished, their expectations of the consequences associated with their actions, and the ways that they understand their behaviors—all of which are importantly shaped by cultural context. In other words, hu-

man motivations are grounded in cultural meaning systems (Bruner, 1990; Shweder, 1990). As such, we should expect motivations to be expressed differently across cultures to the extent that cultures vary in the ways that particular behaviors are rendered meaningful. Here I review the literature on recent efforts to investigate how cultures differ in the ways that motivations are shaped and expressed.

RELIGION AND ACHIEVEMENT MOTIVATION

One of the earliest cultural-psychological theories regarding motivation, and perhaps the most profound, was proposed by a sociologist. In 1904–1905 Max Weber published a highly influential and controversial series of essays entitled *The Protestant Ethic and the Spirit of Capitalism* (1904/1992). Weber recognized a fundamental tenet of cultural psychology that, in contrast to most events in the natural world, human behavior is necessarily interwoven with meaning. Events do not simply impinge themselves upon people; it is people's interpretation of what those events mean that motivates them to respond accordingly.

Weber's theory was developed and explored largely outside of a psychological context; however, specific psychological hypotheses have since been proposed and tested (e.g., McClelland, 1961; Sanchez-Burks, 2002). Given its nonpsychological roots, the theory may be somewhat unfamiliar to many psychologists and warrants some background description. Weber was interested in the question of how the revolutionary doctrine of capitalism was able to emerge out of the traditional economies of the medieval era. At the time that Weber published his ideas, the dominant theory in the social sciences was Marxism, which proposed that capitalism emerged as the result of structural changes in the economy. Specifically, Marx maintained that as industries developed technologies that increased the productivity of workers, the surplus value of workers' efforts accumulated and was reinvested into production. Capitalism was thus seen to follow from industrialization, and, indeed, was viewed as an inevitable consequence of it. In contrast to the economic determinism of Marxism, Weber viewed capitalism as the product of people deriving meaning from a particular cultural context. He proposed that capitalism was built on the foundation of a number of cultural beliefs

that emerged alongside the Protestant Reformation.

Protestantism initially emerged as a reaction to some corruption in the medieval Catholic Church, but Weber maintained that it contained ideas that shaped much more than the spiritual lives of its followers. One idea to emerge from Protestantism was the notion that individuals were able to communicate with God directly, and were not dependent upon the Church as an intermediary. This individualized relation between each person and God has been argued to be central to the blossoming of individualism that emerged during the Reformation and continues to influence much of Western society today (e.g., Baumeister, 1987; McClelland, 1961).

A second idea to emerge was related to this belief in an individualized relation between God and each person. Martin Luther proposed that each individual had a "calling"; that is, each person had a unique, God-given purpose to fulfill during his or her mortal existence. The idea was that people are all God's servants in the world, and that each individual was given a specific duty or job to take care of while he or she tended the planet. God gave individuals unique skills and capabilities to enable them to fulfill their calling, and it was incumbent upon them to discover that calling. People's highest moral duty was to serve God well by working hard at their calling. Weber argued that by developing this notion of a calling, Luther was able to imbue daily labor with a spiritual significance that had traditionally been reserved for religious activities such as prayer and ritual. With the Protestant Reformation, work had thus become a moral obligation rather than something necessary for subsistence. As such, people's attitudes shifted from work as *a means to survive* to work as an *inherently meaningful activity* in itself. This shift in attitudes, Weber maintains, had an enormous impact on the economic development of Protestant nations.

The early Puritan sects of Protestantism (e.g., Calvinism, Methodism, Pietism, and Baptism) also proposed the radical idea of predestination, that is, the belief that it was already determined before one was born whether one was of the fortunate "Elect" who was destined for Heaven, or was one of the wretched many who was doomed to burn in Hell forever. Which fate was one's own was a distinction that no doubt mattered a great deal to the Puritans. Weber submitted the counterintuitive proposi-

tion that this belief in predestination played a key role in the development of capitalism. One might expect that if people's fates were predetermined, then they might respond by deciding to enjoy their lives, because there was nothing that they could do to change their fates. They might as well live it up while the living was good. However, this interpretation was apparently rarely seized upon; rather, the notion of predestination brought with it "a feeling of unprecedented inner loneliness" (Weber, 1904/1992, p. 104), and individuals were highly motivated to escape it by convincing themselves that they were among the privileged Elect. Because people did not know their fate for certain, they had to make inferences based on available cues. The primary cue that one was among the Elect was possessing absolute certainty about this fact, and evidence for this certainty could be seen in the products of one's efforts to fulfill this calling. It was believed that God would not reward those who were doomed to burn in Hell, so any sign of material success was perceived as evidence that one was among the Elect. Furthermore, because one's time on earth was to be spent serving God through one's calling rather than enjoying the fruits of one's labor, any accumulated wealth was to be reinvested to further one's efforts, and to accumulate even more wealth and evidence of one's chosen status. Modern capitalism, as Weber viewed it, was thus concerned with the accumulation of wealth for its own sake, and not for the sake of the material pleasures that it brought. Weber proposed that the combination of beliefs in an individualized relation with God, a calling, and predestination provided the cultural foundation for capitalism.

Weber's thesis has been highly controversial since it was first published. Giddens (1992) described the many ways that people were offended by this theory: Weber's characterizations of Catholicism as having a retarding influence upon modern economic development alienated most Catholics; his description of Puritan life as being bound up in an ecclesiastical straitjacket was not appreciated by Protestants; people of other religious backgrounds felt ignored (there is clear evidence of a moralized work ethic among people of Confucian and Jewish backgrounds, for example, something which Weber (1951, 1952) emphasized in some of his other works); and Weber's contention that religious ideas can transform economies

perturbed the Marxists and most economists. It seems that some were so incensed by Weber's thesis that they were willing to offer some rather far-fetched alternative accounts for the greater economic success Weber identified among Protestants compared to Catholics. For example, Huntington (1915) argued that the relative success of Protestant nations was due to their more temperate climate (with no account offered for the relative lack of success among the more temperate Catholic nations). Fanfani (1935) went so far as to propose, without any supporting data, that people in Protestant nations tend to have longer heads than people in Catholic ones, which somehow allowed Protestants to be more successful.

Despite the continuing controversy, much evidence is consistent with Weber's thesis. Some evidence comes from economists and historians, who note that power and wealth moved in Europe from places such as Spain and northern Italy before the Protestant Reformation began in 1517, to Northern European Protestant centers in Germany, the Netherlands, and England, until its most colossal bloom in the 20th-century United States (e.g., Landes, 1999). A consideration of per capita income among countries of the world revealed that largely Protestant nations earned more than mixed Protestant and Catholic nations, and that these earned more than predominantly Catholic nations (Furnham, 1990). Jackson, Fox, and Crockett (1970) found that Protestants in the United States were more likely to enter high-status, nonmanual occupations than Catholics of the same occupational origin, controlling for a variety of other societal variables. McClelland (1961) found that Protestant nations were far more industrialized than their Catholic counterparts.

There is also much psychological evidence supporting Weber's thesis. McClelland (1961) recognized that Weber's proposal was inherently a theory about motivation, and that one could derive testable hypotheses regarding a greater need for achievement among those raised Protestant than among those raised Catholic. For example, he found that, compared with Catholic parents, Protestant parents expected their children to become self-reliant at an earlier age. Likewise, he compared the stories written by young boys and found that those written by German Protestants had higher need for achievement scores than those written by German Catholics (McClelland,

1961). Various other lines of research have followed McClelland's pioneering efforts. Giorgi and Marsh (1990) found pronounced differences between Western European Catholics and mainstream Protestants in the embracing of an intrinsic work ethic (interestingly, the relation was clear both when contrasting individuals of different religions *within* countries, and when comparing countries) as evidenced in a measure of work values. Furthermore, this relation was identifiable regardless of individuals' level of religiosity, suggesting that the work ethic had become secularized. The Protestant ethic has also been associated with negative attitudes toward laziness and being overweight (Quinn & Crocker, 1999), and a concern with self-esteem and self-deception (which I elaborate on later; Baumeister, 1987; Crocker & Park, 2004).

Sanchez-Burks and colleagues (Sanchez-Burks, 2002; Sanchez-Burks et al., 2003; Sanchez-Burks, Nisbett, & Ybarra, 2000) investigated Weber's thesis in the laboratory. Sanchez-Burks (2002) was interested in exploring an aspect of Protestant ideology emphasized by Calvinism; that is, when Protestants are engaged in their morally sanctioned work, they should be entirely focused on their work, thus maintaining a rather impassive attitude toward potential distractions, such as other people (Bendix, 1977; Hampden-Turner & Trompenaars, 1993). Protestants should maintain a relational style toward others that is relatively detached while they are working; however, in contexts where there are no work obligations, they should switch back into a more attentive relational style (Weber, 1947). Sanchez-Burks (2002) sought to test this hypothesis by comparing Protestants and non-Protestants in two different settings. The participants in his experiment were all European American students raised either as Protestants (specifically Presbyterians and Methodists, the two Protestant sects influenced by Calvinist ideology that were most represented among the student body) or as non-Protestants (Catholics, atheists, and other religious backgrounds). These participants were assigned to engage either in a task in a work environment or a casual nonwork setting. Participants in the two conditions worked together with a confederate of the experimenter who was kept blind to participants' religious background. The confederates were instructed to nervously shake their feet the entire time they were talking with the

participants. The primary dependent variable was a measure of unconscious mimicry (Bargh, Chen, & Burrows, 1996; Chartrand & Bargh, 1999): specifically, how much more the participants shook their own feet when they were with the confederates compared with time when they were alone. Male participants revealed a pattern precisely in line with predictions derived from Weber's thesis (women, Sanchez-Burks argued, tend to maintain more of a relational focus regardless of circumstance); that is, male non-Protestants were just as likely to mimic the confederate's foot shaking in a casual setting as in a work setting. In stark contrast, the Protestant males showed very little evidence of mimicry in the work setting but considerable mimicry in the casual setting. It appears that when Protestant males are focused on a work task they are able to shut out relational concerns, something which neither Protestant women nor non-Protestants seem to do. When Protestant men are actually working, they do not seem to have much interest in anything else.

Fueling the controversy in Weber's thesis, however, are some cross-cultural studies comparing Likert scale means on various self-report measures of the Protestant work ethic that do not appear to be consistent with Weber's thesis. Indeed, studies that have compared the means on these scales reveal either no cultural difference in the Protestant work ethic or a weaker work ethic among nations of a largely Protestant background (e.g., the United States, Australia, and Britain) than among people from countries with little exposure to Protestant ideology (e.g., India, Malaysia, Mexico, Sri Lanka, Uganda, and Zimbabwe; Baguma & Furnham, 1993; Furnham, Bond, & Heaven, 1993; Furnham & Muhiudeen, 1984; Isonio & Garza, 1987; Niles, 1994); that is, the evidence for an association between Protestantism and achievement motivation is far more consistent in laboratory studies (e.g., Sanchez-Burks, 2002), and studies that measure various cultural products associated with the Protestant work ethic (e.g., McClelland, 1961) than in studies that utilize cross-cultural comparisons of means from self-report measures. This is consistent with a growing body of evidence that comparisons of means of subjective Likert scale measures across cultures can be compromised by various response artifacts, such as reference-group effects, and yield results of dubious validity (Heine, Kitayama,

Lehman, Takata, et al., 2001; Heine, Lehman, Peng, & Greenholtz, 2002; Peng, Nisbett, & Wong, 1997).

In summary, to the extent that Max Weber was correct a century ago, we can understand some of people's achievement motivations to be derived from religious ideas that they encounter in their cultures. Weber's thesis remains controversial, however; a great deal of evidence in support of it has been marshaled from a variety of different disciplines. Laboratory investigations of Protestant ideology are relatively new to psychology, and there will surely be further challenges and validations of Weber's thesis in the future.

MOTIVATIONS FOR CONSISTENCY

One of the most central themes in Western social psychology derives from the notion that people are motivated to be consistent. Dating back to Heider (1958) and Festinger (1957), researchers have emphasized the importance that people place on viewing themselves and their behaviors in a way that coheres in a consistent and sensible manner. This motivation can be identified in a number of diverse research paradigms, including cognitive dissonance, self-verification theory, autobiographical memories, and the "foot-in-the-door" paradigm, and is a fundamental assumption underlying personality theory (Mischel, 1973). When people encounter inconsistency, so the theorizing goes, they encounter a problem that needs to be rectified. As the 2004 U.S. presidential election highlighted, it was a costly liability for John Kerry to be perceived as someone who changed his opinions, in contrast to the determined and steadfast George W. Bush. Consistency is a desired end state that people are motivated to achieve.

Although the Western research demonstrates that a motivation for consistency is an extremely powerful drive, it is less clear how well this motivation generalizes to other cultural contexts. In particular, there is a growing body of evidence that consistency motivations are weaker among East Asians. For example, consider the results of a study by Kanagawa, Cross, and Markus (2001). They sought to investigate how much people's context affects the ways that they view themselves. College students from Japan and the United States were asked to complete the Twenty Statements Test;

however, the students' context at the time of the study was varied. Some participants completed the questionnaire in a professor's office; other participants sat next to a fellow student; still others sat in a large group of about 20–50 people, and some students completed the questionnaire alone. Kanagawa et al. calculated the ratio of positive statements that students made about themselves compared to the number of negative statements. They found that the American responses looked quite similar across the four conditions. Their selves were described in pretty much the same way regardless of situation. In contrast, the Japanese responses varied considerably across situations. They were considerably less self-critical when they were by themselves than when they were with others, especially when they were with a professor. The general positivity of Japanese individuals' attitudes toward themselves appeared quite different depending on who was in the room with them. Likewise, other research with the Twenty Statements Test reveals that East Asians tended not to describe themselves by abstracting features across situations, in contrast to American's tendencies to view themselves more in terms of pure psychological attributes (M. H. Bond & Cheung, 1983; Cousins, 1989). Thus, East Asians appear to be more willing than Westerners to describe themselves in divergent ways across different contexts (also see Suh, 2002).

One reason why East Asians appear to be more accepting of inconsistency can be traced to a predilection for what Peng and Nisbett (1999) referred to as "naive dialecticism." In contrast to Western formal reasoning traditions that require that contradictions be resolved, principles of Chinese reasoning recognize contradiction as natural and as something to be accepted. When presented with two apparently contradictory arguments, Westerners appear to accept just one of them, whereas Chinese accept the merits of both (Peng & Nisbett, 1999). This tolerance for contradiction among East Asians generalizes to their self-concepts. Spencer-Rodgers, Peng, Wang, and Hou (2004) found that East Asians are more likely than Westerners to have ambivalent views of themselves, agreeing with statements about themselves that would appear to be contradictory. These contradictory views also generalize to East Asians' personality traits, implicit theories, and attitudes (Hamamura, Heine, & Paulhus, 2007; Spencer-Rodgers, Boucher,

Mori, Wang, & Peng, 2007). Furthermore, when East Asians encountered new, contradictory information about themselves, they were more likely than Americans to accept it and to adjust their self-views (Spencer-Rodgers et al., 2007). In summary, inconsistent beliefs are tolerated more among East Asians than among Westerners.

This cultural difference in a motivation for consistency is not isolated to how people describe themselves and their beliefs. Indeed, social psychology's favorite theory, cognitive dissonance, also reveals pronounced cultural variation. Heine and Lehman (1997) found that whereas North Americans show pronounced dissonance reduction strategies, Japanese showed no tendency to rationalize their decisions after they made them, even when they were confronted with threatening feedback. This absence of a motivation for dissonance among East Asians in standard dissonance paradigms appears to be reliable (also see Hiniker, 1969; Hoshino-Browne et al., 2005; Kitayama, Snibbe, & Markus, 2004). However, East Asians do appear to show some interesting variants on the dissonance reduction process. Hoshino-Browne et al. (2005) found that although East Asians did not rationalize their own decisions, they would rationalize the decisions that they made for other people. Kitayama et al. (2004) found that even though Japanese individuals would not rationalize their decisions in a standard dissonance condition, they showed pronounced dissonance when placed in a subtly activated interpersonal context. It appears that motivations for consistency among East Asians emerge in rather different forms than they do for Westerners. Whereas North Americans appear to aspire for consistency within themselves, East Asians are concerned with being consistent with their behavior in the context of others (also see Cialdini, Wosinska, & Barrett, 1999, for comparable cultural differences between Americans and Poles). Hence, there is a similarity across cultures in motivations to keep something consistent; however, what people endeavor to keep consistent varies importantly across cultures.

As much research has demonstrated, then, North Americans are motivated to be consistent across situations. In general, it is often a useful starting point to assume that traits and practices become common within a culture because they are functional (although there are many clear instances of maladaptive cultural

traits and practices; see Richerson & Boyd, 2005). To the extent that the consistency of self-views serves a function, we should expect that consistency has more favorable outcomes for North Americans than for East Asians.

Suh (2002) tested this hypothesis by exploring the correlates of self-consistency among Koreans and Americans. He found that, for Americans, there were strong positive correlations between consistency and subjective well-being, peer-rated likability, and evaluations of social skills. Apparently, Americans feel better about themselves if they see themselves as consistent, and other people view consistent individuals to be especially socially skilled and likable. In contrast, the correlations with the Koreans were much smaller. Being consistent in Korea was not associated as strongly with feeling good about oneself (see Campbell et al., 1996, for similar findings with Japanese), and it was not associated as much with being perceived as especially socially skilled or likable. Koreans are likely less consistent across situations compared to Americans, because there are fewer benefits in Korea for viewing oneself consistently in this way. The benefits of self-consistency do not appear to be constant across cultures.

MOTIVATIONS FOR SELF-ENHANCEMENT AND SELF-ESTEEM

The motivation that has probably been researched the most across cultures is the motivation to *self-enhance*, that is, a desire to view oneself positively. A great deal of research from a diverse array of methodologies reveals that Westerners apparently have a strong need to view themselves in positive terms. For example, measures of self-esteem reveal that the vast majority of North Americans score in the top half of their scale (Baumeister, Tice, & Hutton, 1989). Indeed, individuals with low self-esteem, operationalized as those with scores below the theoretical midpoint of the scale, are relatively rare in North American cultural contexts (less than 7% of a large European Canadian sample; Heine & Lehman, 2004). In addition, evidence for the positivity of Westerner's self-views can be seen in the common finding that people often exaggerate the positivity of their evaluations; that is, they show self-enhancing biases. Reviews of this literature (e.g., Greenwald, 1980; D. T. Miller & Ross,

1975; Taylor & Brown, 1988) indicate that North Americans' self-perceptions tend to be systematically biased toward an overly positive view of the self. Moreover, the ever-growing body of research on self-evaluation maintenance provides further testimony to the strong motivations that Westerners have for positive self-views. This literature documents the variety of compensatory self-protective responses that are elicited when people encounter threats to their self-esteem. Such strategies include self-evaluation maintenance (e.g., Tesser, 1988), self-affirmation (e.g., Steele, 1988), compensatory self-enhancement (e.g., Baumeister & Jones, 1978), downward social comparison (e.g., Wills, 1981), motivated reasoning (e.g., Kunda, 1990), and self-handicapping (e.g., Tice, 1991). That such a wide variety of self-esteem maintenance tactics exists highlights the importance of maintaining a positive self-evaluation, at least within North American culture, where the majority of this research has been conducted.

This research reveals quite clearly that motivations for positive self-views are powerful and pervasive among Westerners. However, Westerners' tendency to endorse more independent views of self (Markus & Kitayama, 1991a), and much research identifying a pronounced positive relationship between independent self-construals and positive self-views within a variety of different cultures (correlations range between .33 and .51; e.g., Heine, 2003; Oyserman, Coon, & Kimmelmeier, 2002; Singelis, Bond, Lai, & Sharkey, 1999) raises the possibility that such positive self-views would be more elusive in cultural contexts that are less characterized by independence.

Much research has investigated motivations for positive self-views in more collectivist cultures, particularly in East Asian cultures. Overall, the evidence suggests that these motivations are far weaker among East Asians. For example, East Asians score significantly lower than Westerners on various different measures of self-esteem (e.g., Chan, 2000; Feather & McKee, 1993; Spencer-Rodgers et al., 2004), and show less evidence for a diverse array of self-enhancing biases (e.g., Heine & Lehman, 1995; Heine & Renshaw, 2002; Kurman, 2001; Markus & Kitayama, 1991b; Norasakkunkit & Kalick, 2002). Evidence for a variety of self-evaluation maintenance strategies is also weaker among East Asians (e.g., Heine, Kitayama, & Lehman, 2001; Heine, Kitayama,

Lehman, Takata, et al., 2001; White & Lehman, 2005). These cultural differences in self-enhancing motivations emerge remarkably consistently and are highly pronounced. Heine and Hamamura (2007) recently conducted a meta-analysis of self-enhancing tendencies among Westerners and East Asians, and found significant cultural differences in every study for 30 of the 31 methodologies used (the one exception being comparisons of self-esteem using the Implicit Associations Test; Greenwald & Farnham, 2000; Kitayama & Uchida, 2003). The average effect size for the cultural differences across all studies was $d = 0.84$. Furthermore, whereas the average effect size for self-enhancing motivations was large ($d = 0.86$) within the Western samples, these motivations were largely absent among the East Asian samples ($d = -0.02$) with Asian Americans falling in between ($d = 0.33$). Apparently, East Asians possess little motivation to self-enhance (Heine, Lehman, Markus, & Kitayama, 1999).

However, it is possible that East Asians really are just as motivated as Westerners to evaluate themselves positively, but that various Western biases in the research methodologies employed have prevented researchers from reliably identifying these motivations. For example, one possibility is that East Asians are more motivated to enhance their group selves rather than their individual selves, and comparisons of people's individual self-enhancing tendencies thus obscure their group self-enhancing motivations. The reasoning behind this alternative hypothesis appears compelling; however, many studies reveal that Westerners show stronger motivations than East Asians to enhance their group selves as well (e.g., Heine, 2003; Snibbe, Markus, Kitayama, & Suzuki, 2003), which challenges this account. Another possibility is that East Asians value a different set of traits than what has been explored in research thus far, and that if they were asked to evaluate themselves on traits they viewed to be especially important, the cultural differences would be reduced. Although some evidence supports this alternative account using the "better-than-average effect" paradigm (e.g., Brown & Kobayashi, 2002; Sedikides, Gaertner, & Vevea, 2005), other methodologies reveal that East Asians are more self-critical for especially important traits (e.g., Heine & Lehman, 1999; Heine, Kitayama, Lehman, Takata, et al., 2001; Kitayama, Markus, Matsumoto, & Norasakkunkit, 1997; for a complete meta-

analysis on this topic, see Heine, Kitayama, & Hamamura, in press). Moreover, when a cognitive bias (“Everybody is better than their group’s average effect”; Klar & Giladi, 1997) is controlled for in the “better-than-average effect” paradigm, the relation between trait importance and self-enhancement is no longer evident among East Asians (see Heine & Hamamura, 2007), suggesting that this observed relation is largely a cognitive bias as opposed to evidence of self-enhancement. A last alternative account to consider is that East Asians are just feigning modesty in these studies (and perhaps Westerners are feigning bravado; see Kurman, 2003; Suzuki & Yamagishi, 2004), and that their private self-feelings are just as positive as they are for Westerners. However, that these cultural differences are at least as pronounced in anonymous situations that employ hidden behavioral measures (e.g., Takata, 2003; Heine, Kitayama, Lehman, Takata, et al., 2001), renders this account less plausible. One piece of evidence in support of this alternative account is the lack of cultural differences found with the Implicit Associations Test measure of implicit self-esteem (e.g., Kitayama & Uchida, 2003). Although it is not yet clear what implicit self-esteem indicates, I would suggest that it likely taps into an affective feeling toward the self, and that East Asians and Westerners “like” themselves to a comparable extent. To the extent that this is the case, this suggests that self-criticism has fewer negative affective consequences in East Asian contexts than in Western ones (e.g., Heine & Lehman, 1999; Kitayama & Uchida, 2003). Overall, the research provides converging evidence that East Asians do not have as strong a desire as Westerners to view themselves positively.

One question to consider is how might this cultural difference in self-enhancement emerge? A proximal answer could be that these motivations are learned from experiences that individuals have while they are young. One source of evidence in support of this comes from a study by P. J. Miller, Wang, Sandel, and Cho (2002; P. J. Miller, Wiley, Fung, & Liang, 1997), in which parents in Taiwan and the United States were interviewed regarding their attitudes toward child rearing. The researchers found that the stories more often told by European-American parents to their children focused on a past success of the child. In stark contrast, the Taiwanese parents were more

likely to tell stories about past transgressions of the child (P. J. Miller et al., 1997). When researchers explicitly asked parents what they thought about self-esteem, answers between the two groups were highly divergent (P. J. Miller et al., 2002). The European American parents viewed self-esteem as central to child rearing and saw it as a positive quality that enhanced children’s development, and something that should be cultivated by parents. The Taiwanese parents, in contrast, had little to say about the words that most closely approximated self-esteem (it is perhaps telling that there is no direct translation of *self-esteem* in East Asian languages), and what they did have to say about it was often somewhat negative; for example, in expressing the belief that too much self-esteem could lead to frustration when things were not working out well for the children. Similar to this cultural difference in children’s experiences with their families, North American schools are more likely than their East Asian counterparts to make efforts to inculcate self-esteem (e.g., Lewis, 1995; Stevenson & Stigler, 1992). In summary, cultural environments in North America and East Asia provide different opportunities for learning ideas regarding whether positive self-views are desirable.

However, a more distal answer to the question of the origins of cultural differences is also needed, because the data I have presented do not address how parents and schools in the different cultures arrived at their respective views. One way to consider how these cultures came to differ in their predilections for self-enhancement is to look at the emergence of motivations for positive self-views over history. Baumeister (1987) explored Western literature across the centuries and submitted that the notion of individual selves was not evident in the texts until the 12th century, when the Christian concept of the last judgment changed from being an issue of salvation of collectives to the salvation of individual souls. It was not until the 16th century and the birth of the Protestant Reformation, however, that something akin to self-enhancing motivations first became clearly evident in literature. The Calvinist doctrine of predestination burdened people with a great deal of psychic anxiety at not knowing whether they were doomed to spend the rest of eternity burning in Hell. With such an enormous, and ultimately unknowable, threat lurking in the back of their minds, people were motivated to

grasp at any shred of evidence suggesting that they might be among the Elect, and motivations for self-deception and self-enhancement grew accordingly (Pye, 2000; Weintraub, 1978).

More recently, there is evidence for growing motivations for self-enhancement within the United States. Twenge and Campbell (2001) conducted a meta-analysis of studies that measured self-esteem among American college students using the Rosenberg Self-Esteem Scale (Rosenberg, 1965). Over a 30-year period, college students' self-esteem consistently rose to the point that participants in the most recent studies had self-esteem scores that were larger than those in the earlier studies by an effect size of approximately $d = 0.60$. Given the relation between independent self-views and self-esteem, discussed earlier, this might be further evidence that the United States has become more individualistic since the end of World War II (e.g., Putnam, 2000; Rosen, 1998). Historical research is relatively new to psychology, and much remains unknown about the reasons underlying changes in self-enhancement motivations over time; however, this is an important avenue to explore in understanding the origin of cultural differences.

MOTIVATIONS FOR FACE AND SELF-IMPROVEMENT

Another way to address the question of why motivations for positive self-views vary across cultures is to consider the different kinds of positive views that one might desire. One way of having a positive self-view is to have high self-esteem; that is, the individual views him or herself positively. Another way of having a positive self-view is to have a good deal of "face," which is an interesting concept that is of considerable importance in much of the world, although it receives much less attention among Westerners. Indeed, the expression "to lose face" did not enter the English language until the late 19th century as a direct translation from Chinese (*Oxford English Dictionary*, 1989). Face has been defined as the amount of social value that others grant you if you live up to the standards associated with your position (e.g., Ho, 1976). In hierarchical collectivist societies, such as the kinds found in East Asia, face takes on special importance (H. C. Chang & Holt, 1994). What is prioritized is not how positively people think of themselves, but

whether significant others think they are doing well. If others grant an individual face, he or she will enjoy all the benefits that come with the enhanced status and power. In such a cultural context, people can become highly motivated to maintain and enhance their face (Heine, 2005).

An important characteristic of face is that it is more easily lost than it is gained. Because the amount of face that people have access to is determined by their position, they cannot readily increase their face, unless they are promoted to a higher position. This renders face as something that is difficult to enhance. However, face is lost whenever an individual is perceived to fail to live up to the standards of his or her role (Ho, 1976). One is therefore always vulnerable in public situations, and because others determine one's face, one must count on the goodwill of others to be able to maintain face. Given that face is so easily lost, it seems that a good strategy would be to adopt a very cautious approach and try to ensure that one is not acting in a way that might lead to rejection by others (Heine, 2005). If one can attend to any potential weaknesses and work toward correcting them by improving oneself, this should decrease the chance that others would view one as having lost face (Heine, Kitayama, Lehman, Takata, et al., 2001).

This kind of defensive, cautious approach to not losing a resource is consistent with a prevention focus, that is, an orientation toward avoiding negative outcomes. This is in contrast to a concern with enhancing the positivity of one's self-view, which is consistent with a promotion focus, that is, a concern with achieving positive outcomes (Higgins, 1996). If a concern with face leads to a prevention orientation, and East Asians are more concerned with face, then we should expect to see greater evidence of prevention orientations among them. Much research has confirmed this pattern (e.g., Elliot, Chirkov, Kim, & Sheldon, 2001; Ip & Chiu, 2002; Lockwood, Marshall, & Sadler, 2005). For example, A. Y. Lee, Aaker, and Gardner (2000) asked Hong Kong Chinese and Americans to rate the importance of some tennis games. The Chinese saw games that were framed as opportunities to avoid a loss as more important than those framed as opportunities to win, and the Americans showed the opposite pattern.

If one has a promotion focus, one should focus efforts on things one is good at, because

these will provide more opportunities for success. Things that one is not good at, in contrast, should be avoided, because they are not likely to lead to success. In contrast, if one has a prevention focus, one should focus efforts on things that one does badly, because correcting shortcomings will help one to avoid future failures. This suggests that East Asians should respond quite differently than Westerners to successes and failures. Heine, Kitayama, Lehman, Takata, et al. (2001) had Japanese and Canadian participants come into the laboratory, where they received private feedback that they had done poorly on a creativity test. Participants were left alone in a room with another set of creativity items, and how long they persisted on this task was timed. The Canadians persisted significantly longer after success than after failure, a finding that replicates much of the work on persistence research in the West (e.g., Feather, 1966; Pyszczynski & Greenberg, 1983). In stark contrast, the Japanese persisted significantly longer after failure than after success. Apparently, the Canadians were more interested in working on what they were good at, what would more likely provide them with opportunities to view themselves positively. The Japanese, in contrast, were more interested in working on the things they did badly, apparently so that they could improve themselves and be less likely to fail in the future. This *self-improvement* motivation, a desire to seek out potential weaknesses and work on correcting them, is a strong motivation in East Asian contexts (e.g., Hoshino-Browne & Spencer, 2000; Kitayama et al., 1997). Interestingly, this cultural difference has even been shown to influence people's choice of leisure activities. Oishi and Diener (2003) found that when given a choice to play either basketball or darts, European Americans tend to choose the activity they are good at, whereas Asian Americans do not. Whether one is primarily concerned with focusing on positive aspects of the self or focusing on areas of the self that need improving affects the kinds of choices people make in their lives.

AGENCY AND CONTROL

All organisms have needs and desires, and must work within the constraints and affordances of their environments to achieve them. Unlike other organisms, humans live in cultural envi-

ronments, which has significant consequences for how they strive to achieve their needs and desires. People have theories about how they can exert control within particular contexts, and those theories are shaped importantly by cultural learning. People strive to achieve their needs and desires in ways that are consistent with their theories for exerting agency in specific ways.

One theory that people possess, which is relevant to their experiences of control, is whether they perceive their selves to be easily malleable and changeable or stable and fixed. Dweck, Hong, and Chiu (1993; Dweck & Leggett, 1988) term these two implicit theories *incremental* and *entity* theories of self, respectively. In addition to the implicit theories that people possess about the malleability of the self, they also have implicit theories about the malleability of the world. For example, people can see the world as something fixed and beyond their control to change (an entity theory of the world), or they can think of the world as flexible and responsive to their efforts to change (an incremental theory of the world). To the extent that people from different cultures perceive selves and their social worlds to be more or less fluid and malleable, they will possess different theories about how individuals can, should, and do act.

Su et al. (1999) offer a nice metaphor to capture the potential ways that people's selves and social worlds can be malleable: Imagine that someone is building a stone wall. There are a couple of different approaches that they could attempt. One is to emphasize the integrity of the wall at the expense of the individual stones; that is, people could have a clear plan of the shape of the wall that they want to maintain and choose stones of approximately the correct size, then carve them down so that they fit perfectly into the wall. The stones would change to accommodate the wall. An alternative way to build the wall would be to allow the wall to take on the shape of the individual stones. People could choose stones of roughly of the right size and shape and assemble them into a wall. The wall would change in shape to reflect the nature of the individual stones. The enterprise of stone wall building will vary a great deal depending on whether one views the individual stones or the resultant wall as flexible and capable of being changed.

As in this metaphor, there are occasions in which there are clear social constraints to

which individuals must adjust themselves, and there are occasions in which social relationships and organizations change to adjust themselves to the nature of their individual members. Although it would seem to be the case that everyone must sometimes view their individual selves as more flexible than their social worlds, and sometimes see their social worlds as more malleable than themselves, the extent to which these beliefs are embraced can vary importantly across cultures.

Primary and Secondary Control

Rothbaum, Weisz, and Snyder (1982) proposed that there are at least two ways that people can gain control in their lives. People achieve a sense of *primary control* by striving to shape existing realities to fit their perceptions, goals, or wishes. This construct captures how most researchers studying control have operationalized it. Much less studied is *secondary control*, which people achieve when they attempt to align themselves with existing realities, leaving the realities unchanged but exerting control over their psychological impact.

Although everyone experiences primary and secondary control on occasion, cultures differ in the extent to which people engage in these two strategies. In hierarchical, collectivist cultures, such as in East Asia, the social world remains somewhat impervious to efforts by a lone individual to change things (e.g., Chiu, Dweck, Tong, & Fu, 1997). Power and agency tend to be concentrated in groups or as mandated by the role that an individual occupies; thus, there are many domains in which people are unable to exert much direct influence. Likewise, East Asians are more likely to have a flexible and incremental view of themselves (Norenzayan, Choi, & Nisbett, 2002), although the evidence for this is more consistent with experimental manipulations and measures of concrete responses than with comparisons of means on Likert score measures (Heine, Kitayama, Lehman, Takata, et al., 2001). When the self is perceived to be more mutable than the social world, it follows that people would be quite willing to adjust themselves to fit in better with the demands of their social worlds.

In contrast, people from Western cultures tend to stress the malleability of the world relative to the self (Su et al., 1999). God told Adam that he would have dominion over all the earth;

the world was there for humans to change and use to their liking. This belief persists in the West, manifest in the view that the individual has potential control in shaping the world to fit his or her own desires. When people view individuals to be the center of experience and action, they accordingly look to individuals as a source of control. Moreover, the independent self is experienced as relatively immutable and consistent (Heine, Kitayama, Lehman, Takata, et al., 2001; Suh, 2002). This view that the self is an immutable entity, working within the context of a mutable world, sustains a perception of primary control.

Weisz, Rothbaum, and Blackburn (1984) make the case that many socializing experiences in Japan lead Japanese people to be more comfortable with engaging in secondary control strategies. For example, Japanese infants spend much more time in contact with their mothers; thus, they learn to adjust themselves to what their mothers are doing. Japanese workers change jobs far less frequently than their Western counterparts, and it was not uncommon for workers to be promised lifetime employment—a system which ensures that employees learn to adjust themselves to whatever demands the company places on them. Weisz and colleagues propose that these and other socialization experiences lead people to seek strategies of control that are most likely to lead to beneficial consequences within the constraints of their respective cultural environments.

Morling, Kitayama, and Miyamoto (2002) investigated whether control strategies differed between Japanese and Americans in line with the hypotheses of Weisz and colleagues. In one study, participants were asked to list occasions when they had tried either to influence people or objects that surrounded them (i.e., primary control experiences) or to adjust themselves to these people or objects (i.e., secondary control experiences). Americans were better able to recall influencing situations than adjusting ones, whereas Japanese remembered more adjusting situations than influencing ones. In this respect, the term “secondary control” might be somewhat of a misnomer in Japan, because this type of control may be more common there than “primary control.” Furthermore, although both Japanese and Americans evaluated influencing situations to have felt more powerful than adjusting ones, suggesting that primary control might universally be experienced as

powerful, Japanese reported feeling more powerful about their adjusting situations than did the Americans. This cultural difference was evident in the way that participants described their adjusting experiences. For example, Americans were more likely than Japanese to report feeling that they were compelled to adjust, as though it was against their will. They often described their experiences as something that they “had to do,” for example, “I had to adjust last school year when my roommate’s boyfriend moved into our house.” In contrast, the Japanese rarely indicated that they felt compelled to adjust, or that the adjustment experience was negative. In summary, experiences of primary control seem to be more frequent among people from Western than from Eastern cultural backgrounds, and a variety of other studies yield comparable findings (e.g., M. H. Bond & Tormatzky, 1973; W. C. Chang, Chua, & Toh, 1997; Seginer, Trommsdorff, & Essau, 1993).

Being part of a group can mean that an individual must sometimes go along with others as a means to get along well. Secondary control strategies are effective ways to manage one’s successful functioning in group contexts. However, if people spend a great deal of time thinking about how they are members of groups, and thinking of others in terms of the groups to which they belong, they might also come to think of control in a different way; that is, they might start to perceive groups as agents, as entities that can make decisions and exert control. Do people in collectivistic cultures see groups as agents in similar ways that people in individualistic cultures see individuals as agents?

This question was investigated by Menon, Morris, Chiu, and Hong (1999). One way that they considered the role of group agency was to see how newspapers in different countries referred to the agents in scandals involving rogue traders. For example, the British stock trader Nick Leeson was convicted in 1995 of fraud when he was involved in a scandal that resulted in the loss of over \$1 billion and the ultimate collapse of his employer, Baring’s Bank. Menon and colleagues were interested in how newspapers in the United States and Japan (specifically, the *New York Times* and *Asahi Shinbun*) reported on this and various other rogue trader scandals in the news. Did the reporters describe the problem as ultimately lying within an individual, such as Nick Leeson, or did they de-

scribe the problem as being due to the management of an organization, such as Baring’s Bank? The articles written about the scandals were analyzed with respect to the frequency with which they addressed the individuals involved or the organizations that employed them. The *New York Times* was more likely to explore the scandals in terms of the problems with the individual trader. In stark contrast, however, the *Asahi Shinbun* focused its reporting on the problems inherent in the organizations that could allow this scandal to occur. Apparently, Japanese are more likely to see events in the world as occurring due to the behaviors and decisions of groups, whereas Americans tend to understand events in terms of the individuals involved. Menon and colleagues further demonstrated how robust this cultural difference was by showing in another study that cultures differed in their explanations of not only human behaviors but also of animal behaviors. They found that Americans were more prone to explain a rancher’s accident in terms of the behavior of a rogue cow, whereas Chinese preferred to explain the same accident in terms of the unruly behaviors of the entire herd (however, note that Ishii & Kitayama, 2005, provide evidence that dispositional inferences for group behavior are similar among Americans and East Asians). The same event can be understood quite differently depending on one’s view of agency.

Making Choices

One way that people can exercise control over their worlds is by making choices. People make countless choices every day and in doing so they structure their lives to match up to their desires. Making choices is perhaps the most direct way that people engage in primary control strategies.

Choice is something that is surely valued everywhere; however, the extent to which people value choice, and exercise it, is influenced by the contexts in which people find themselves. People in individualist societies are less dependent on the actions of others than those in collectivist ones. People in collectivist societies should, on average, be more concerned with the goals of their groups, and, as such, be more willing to adjust their behaviors (and reduce their choices), so that they can coordinate the actions of the group toward those goals. One stark example of this cultural difference is that

in many collectivist cultures today (and perhaps in nearly all cultures several centuries ago), critical life decisions, such as who one would marry or what job one would pursue, have been made by families rather than by the individuals themselves (e.g., G. R. Lee & Stone, 1980).

Iyengar and Lepper (1999) explored how children from different cultural backgrounds would respond to situations in which they made choices on their own or had the choices made by someone else. They recruited fifth-grade students of European and Asian ancestry from two elementary schools in the San Francisco Bay area, and randomly assigned the students to play a computerized math game in one of three conditions. In a "personal choice" condition, students were allowed to make a number of choices that were all irrelevant to their success in the game. For example, they could choose which of four icons would represent their spaceship, and which of four names they would give to their spaceship. In an "outgroup choice" condition, students saw the same four options for the spaceship icons and possible names; however, they were told that the choices had already been made for them by students from another school. Last, students in an "ingroup choice" condition were shown the same options and were told that they were assigned to a particular spaceship, because that was what most of their classmates had wanted. All the students then had the opportunity to play the game, and their persistence was assessed. The students of European background attempted the most games when they got to choose their own space ships. They played significantly fewer games when either the students from the other school or their classmates made their choices for them. In contrast, Asian American students attempted the most games when their classmates chose their space ships for them. However, like the European Americans, they were not very motivated when an outgroup member made their choices for them. Apparently, Asian Americans viewed the situation of their ingroups making choices for them as opportunities to promote harmony and a sense of belongingness with other group members. European Americans seemed to view the same situation as something that stripped them of their freedom to choose. Thus, how people feel when close others make choices for them varies a great deal across cultures.

There is also evidence of cultural variation in perceptions of control within individualist

cultures. The vast majority of psychological research is conducted with a limited sample that is not only largely restricted to participants from Western cultural backgrounds but also usually further limited to college students from those same cultural backgrounds (Sears, 1986). College students are not necessarily representative of humankind. For example, they differ from the rest of the population in that they are more likely to be from upper-middle-class backgrounds and are more likely themselves to raise their own families in an upper-middle-class environment compared with non-college-educated people.

How might we expect people of upper-middle-class backgrounds to differ in their perceptions of control than those from working-class backgrounds? One obvious way is that working-class people earn less money and, because of that, have fewer choices available. Working-class people also have different kinds of relationships compared with upper-middle-class people (they tend to have fewer friends, to live closer to them, to have more frequent contact with kin, and to rely more on kin for material assistance; Allan, 1979; Markus, Ryff, Curhan, & Palmersheim, 2004). Working-class adults participate in a different cultural world compared with upper-middle-class adults, and they are more likely to face hardships in their lives, and to have less control over these hardships than do upper-middle-class adults.

Snibbe and Markus (2005) explored differences in control experiences by comparing working-class and upper-middle-class Americans. In one study, they asked people at a shopping mall to complete a questionnaire, for which they were offered a pen as compensation. In a "free choice" condition, the experimenter let participants choose any pen they wanted. In a "usurped choice" condition, participants were allowed to choose a pen; however, after making their choice, the experimenter said, "I'm sorry. You can't have that pen. It's the last one of its kind that I have. Here, take this one." The experimenter then replaced their chosen pen with the same kind of pen that the previous participant in the "free choice" condition had chosen. At the end of the questionnaire, participants were asked to evaluate the pen that they had received. The working-class participants in the usurped choice condition were almost as satisfied as they were with the pen that they received in the

free choice condition. In contrast, however, the upper-middle-class participants were significantly less satisfied when their choice had been taken away from them. Snibbe and Markus argue that upper-middle-class Americans are raised to favor choices, and to express themselves through their choices. As such, they learn to respond quite negatively whenever they perceive that they do not have any choice in a situation. In contrast, working-class Americans grow up learning that much of what they encounter in life is beyond their control, and that a good way to maintain their independence is to emphasize their integrity and resilience during tough times. This orientation leads to an outlook to accept and cope with occasions where they do not end up with what they wanted. Several other studies conducted by Snibbe and Markus further support their case. Even within an individualized culture, we can see clear differences in people's perceptions of choice and control.

MOTIVATIONS TO FIT IN OR TO STICK OUT

In many occasions when people are deciding how to behave in a group of others, they can decide to go either of two ways. First, they can strive to act in a way that fits in well with others, thereby increasing group harmony at the expense of their own individual distinctiveness. Alternatively, they can decide to act in such a way that they stick out from others, highlighting their uniqueness at the potential risk of not getting along so well with others. People are often in the position to make such a decision, and the way they reach their decisions is influenced by their cultures.

Perhaps the most dramatic explorations of how people make decisions on whether they should fit in or stick out were conducted by Solomon Asch (1956), using his famous conformity paradigm. Participants were faced with a decision of either stating what they saw, and thereby contradicting a unanimous group of confederates who had already expressed a discrepant view, or of going along with the group and ignoring what they had seen with their own eyes. In his studies, Asch found that most Americans would conform at least once in the context of this paradigm.

Asch argued that people conformed in this experimental design because of a desire to be accepted by others, reflecting the normative in-

fluence of conformity. People tend to fare better when others do not view them negatively and reject them. The social costs of dissenting would seem to be considerably greater in collectivist societies, in which people have more obligations with their ingroup members and a stronger motivation to achieve a sense of belongingness. The Asch conformity paradigm has been immensely influential, and it has been replicated well over 100 times in 17 different countries. A meta-analysis of these studies revealed one clear trend: Although Americans show a great deal of conformity in this paradigm, people from more collectivist cultures conform even more (R. Bond & Smith, 1996). Conformity was particularly pronounced among people from collectivist cultures when people were conforming with decisions made by their ingroups. Motivations to fit in are stronger in cultural contexts that encourage people to maintain strong relationships with others (although it is possible that there are weaker cultural differences for informational conformity).

In contrast to a motivation to conform, we can also consider people's motivations to stick out and to be unique. People with independent views of self see their identity as ultimately grounded in their individual qualities. Their identity is not so much shared with others and is perceived to be fundamentally unique. Maintaining a view of oneself that is consistent with cultural values of independence, then, should be aided by striving to view oneself as a unique and special individual. Thinking of oneself as unique highlights that one really is separate from others.

In contrast, people with interdependent views of self see their identity as ultimately grounded in their relationships with significant others. Identity is experienced as shared; thus, there should be less motivation to view oneself as separate and distinct from those important others. Aspiring for a view of self that emphasizes one's interdependence should be aided when individuals do not view themselves as especially different. Being different suggests that one might not be fitting in as well. As such, we should expect to find that people with interdependent views of self would be less motivated to see themselves as unique compared with those with independent views of self.

Kim and Markus (1999) investigated this hypothesis with a clever study. Participants of European and Asian descent were recruited at an

airport and asked to complete a questionnaire. In return for their time, they were offered a pen. The experimenter had a bag full of red and green pens, and would reach down and pull out a handful (five) of them, and ask the participant to take a pen of his or her choice. This ensured that all participants had to make a choice between pens of two different colors, and that they also had to choose between pens that were either of a majority color (three or four pens of the same color) or of a minority color (one or two pens of the same color). The findings revealed that the European Americans were much more likely to choose the pen of the minority color. In stark contrast, East Asians were more likely to choose the pen of the majority color. Apparently, the European Americans maintain a desire to express their uniqueness by making what they think are unique choices, whereas East Asians maintain a desire to express their belongingness by making what they think are common choices. Other analyses, and other studies that Kim and Markus conducted, corroborated that this is why the people made these divergent choices (also see Kim & Drolet, 2003).

Motivations for uniqueness are therefore quite different between these two cultural groups. An important question to consider is how these particular motivations, and cultural ideas more generally, came to be so widespread within cultures, yet so different between cultures. Kim and Markus (1999) were interested in this question when studying cultural differences in motivations for uniqueness. They felt that one way to observe these different motivations being communicated would be to look at messages in advertisements. The kind of message that would be most persuasive would reflect ideas widely shared within a culture. Kim and Markus investigated the commonness of themes that expressed either uniqueness or conformity in magazine advertisements in Korea and the United States. They looked at several categories of magazines (business magazines, women's magazines, etc.) from each country and took note of each advertisement they encountered. They coded each ad with respect to whether it contained a theme for conformity (e.g., "Seven out of 10 people are using this product") or a theme for uniqueness (e.g., "Ditch the Joneses"). They found that uniqueness themes were more common in American ads than in Korean ones, and that conformity themes were more common in Korean ads than

in American ones. This suggests that the kinds of cultural messages that people encounter on a day-to-day basis are helping to reinforce the different views of self in the two cultures.

CONCLUSION

To have a rich understanding of how people are motivated it is necessary to understand the cultural contexts that afford and constrain the kinds of things that people will pursue. Although all of the motivations discussed in this chapter are likely understood and experienced by people from all cultures (i.e., they are all existential, if not functional, universals; Norenzayan & Heine, 2005), the degree that they are emphasized, and whether they are prioritized, varies considerably, as the previously discussed research demonstrates. People from different cultures vary in their motivations, because they have become attuned to the different contingencies associated with those motivations. For example, when individuals are participating in a context in which the benefits of fitting in far outweigh the costs, they will likely become especially motivated to fit in when in that context. To the extent that individuals usually find themselves in such contexts, and rarely find themselves in contexts in which greater benefits can be derived from sticking out, an orientation toward seeking ways to fit in should become routinized and prioritized for them. Furthermore, if individuals are continually surrounded by others who are also habitually attending to fitting in, because they too more often find themselves in contexts where such an orientation is facilitated, an emphasis on fitting in will likely become a norm that serves to guide how individuals value fitting in more generally. Because cultures differ precisely in the kinds of situations they provide their members, people in different cultures come to be motivated in importantly divergent ways. In these ways, culture and psyche come to make each other up (Shweder, 1990).

CHAPTER 30

The Cultural Psychology of Emotion

BATJA MESQUITA
JANXIN LEU

Since Darwin's time, many scholars have seen emotions as a functional adaptation to social living (Ekman, 1992; Oatley & Jenkins, 1992; Tooby & Cosmides, 1990, 1992). Emotions signal the occurrence of pressing social problems or opportunities and provide heuristics for successful behavior (Oatley & Jenkins, 1996). One of the prime reasons that emotions have likely evolved is to monitor and negotiate our social relations.

These social relations vary across cultural contexts. Human beings do not live in uniform worlds. Therefore, their emotions are not, or not most of the time, responses to universal emotional events. Human emotional behavior is not aimed at achieving general, universal goals. Rather, human beings always live in specific environments. As the anthropologist C. Geertz puts it:

People who are independent of time, place, and circumstance do not now and have not ever existed, and by the very nature of things could not exist. . . . Becoming human is becoming individual, and one becomes individual under the guidance of cultural patterns and historically created systems of meaning in terms of which we give form, order, point, and direction to our lives. (1973, p. 49)

In other words, human beings always function in a specific cultural space, and emotions help navigating this cultural space.

Both the particular relationship arrangements and the meanings that animate and justify these arrangements vary across cultures. Successfully navigating the cultural space means specifically engaging in relationships with other people. Therefore, emotions have to signal culturally relevant relational opportunities and problems, and motivate a culturally appropriate and effective course of action. For example, an emotion signals a *particular* threat that derives its meaning from the cultural relational arrangements and their meanings—the threat of losing honor, for example—rather than merely danger in general. Similarly, the action motivated by this threat is the type of escape or preventive behavior that, given the particular cultural practices of relating, makes sense and has a good chance for success—avoiding contact with men, for example, when you are a Bedouin woman (Abu-Lughod, 1986). The behavior is not escape in general. In summary, the functionality of emotions within a sociocultural context requires that they be coordinated with the specific cultural meanings and practices.

We conceptualize emotions as multifaceted, open phenomena that are shaped to be effective in the sociocultural context in which they occur. The primary facets of emotion are emotional experience, which, among others, is constituted by the appraisal of the situation and action readiness, expressive behavior, autonomic and central nervous system changes, and behavior. Our conceptualization of emotions is markedly different from the commonly held view that emotions are invariant states that, when triggered, manifest themselves in preprogrammed ways. By considering the fit of emotions into their cultural environment, we take a socioculturally functional view.¹ This chapter reviews the evidence for systematic cross-cultural differences in emotional experience as they are mutually constitutive with the cultural meanings and practices in which they occur.

CULTURAL MODELS

The central thesis of this chapter is that emotions within a sociocultural context must accommodate the specific meanings and practices (Bruner, 2003), particularly those of self and relationships. We describe these meanings and practices as *cultural models* (for similar constructs Bruner, 1986, 1990; D'Andrade, 1984; D'Andrade & Strauss, 1992; Holland, Lachicotte, Skinner, & Cain, 1998; Holland & Quinn, 1987; Markus, Mullally, & Kitayama, 1997; Shweder & Haidt, 2000).

Cultural models are not so much verbal propositions as ways that reality, including the psychological reality, is defined. These models reflect and foster the types of personhood and relationships that are sanctioned and condoned. They are manifest in everyday social interaction, the language, the public messages as conveyed by the media, books and educational policies (Markus et al., 1997) and, as we argue in this chapter, in emotions. In each of these reality-constituting practices, certain ways of being and certain types of relating to others are afforded, expected, or shaped. A cultural model is decisive for what a person's world is like (Bruner, 1986), because it constitutes the means by which people make sense of and coordinate their feelings and actions alone and in concert with one another. Although cultural models are typically invisible to those that engage or

enact them, they can be made more explicit in comparing different cultural models.

Throughout the chapter we describe specific cultural models as they become manifest in emotional experience. Most research compares emotion in North American and Japanese contexts. North American independent models highlight the boundaries of each individual, whereas interdependent Japanese models assume the mutual interdependence of people in relationships (Markus & Kitayama, 2003; Triandis, 1995). Consistently, emotions in independent, American contexts seem to highlight the individual as bounded, autonomous, and self-sufficient, and often entail influencing relationships in ways that reinforce the individual's autonomy. On the other hand, emotions in interdependent, Japanese contexts highlight and express the relatedness between people, and further action that leads to a strengthening of interpersonal bonds (Kitayama, Mesquita, & Karasawa, 2006; Markus & Kitayama, 1994; Mesquita et al., 2005).

The comparison of independent North American and interdependent Japanese contexts has revealed that the patterns of emotional experience and behavior are subject to substantial variance. Thus, this comparison has demonstrated the plasticity of emotions, and has made a substantial contribution. It would be wrong to assume, on the basis of this research, that there are two ways of having emotions, an independent and an interdependent way. The scant evidence on emotions in non-East Asian interdependent cultures suggests that emotions in different interdependent cultures can be experienced in very different ways, and the same might be true for independent contexts other than mainstream North America. For example, research conducted among Mexicans, both those living inside and outside of the United States, suggests that emotions in Mexican interdependent contexts differ dramatically from those in Japanese interdependent contexts (discussed later in the chapter). Therefore, understanding the cultural shaping of emotion requires moving beyond the dimensions of independence (individualism) and interdependence (collectivism) to the more detailed cultural models of self and relating. A detailed analysis of the functional role of emotions in specific social contexts is necessary.

Importantly, we postulate that cultural models of self and relating afford and constraint

emotional experience and behavior (Miller, 1997). In contrast to what some authors have suggested (Matsumoto & Yoo, 2006), this is not the same as claiming that emotion representations are caused by culture or, in this case, by cultural models of self and relating. We do not conceive of culture as the independent variable and emotion as the dependent variable. Culture is not an entity, and it cannot, in that sense, be responsible for another entity, emotion. Rather, we see patterns of emotion as phenomena that constitute culture (Adams & Markus, 2004). The prevalent patterns of emotion differ across sociocultural contexts that may be demarcated by not only national boundaries but also age, religion, class, or gender. This way of viewing culture as *constituted by the prevalent emotion patterns* does not imply a strict homogeneity between the people within a cultural context.

EMOTION AND EMOTIONAL EXPERIENCE

Emotions are central to social life (Frijda & Mesquita, 1994; Keltner & Haidt, 1999). Among other functions, they reflect the meaning a given social context has to an individual, and they are heuristics for action, predisposing an individual toward action that promotes certain end goals. Thus, emotions can be seen as links between the person and his or her environment. We postulated earlier that emotions must reflect the cultural models in which they occur, because the personal and social meaning of social episodes and the desired personal and social end states are implicated in the cultural models of self and relating.

Cultural shaping of emotions does not necessarily imply that everything about the emotion is culturally learned. It is possible and likely that the potential for particular aspects of emotion, such as certain configurations of the face, or certain physiological responses, is hardwired. The extent to which this is the case has yet to be empirically established in full. However, the existence of hardwired responses in no way negates the cultural constitution of emotions. The combinations, rates of occurrence, and meanings of hardwired responses, and “what it is like to have an emotion,” should be expected to vary widely, in ways that are consistent with the cultural model.

We would expect that cultural models shape responses at every level of the emotion: the

appraisal of the event, action readiness, bodily changes, expressive and instrumental behavior, and conscious regulatory processes. Our view is different, therefore, from the one proposed by Levenson Soto, and Pole (Chapter 32, this volume). We would predict that cultural differences emerge in each of the components, provided—and this is an important and often overlooked clause—that emotions are studied in contexts that are *relevant* to the cultural models, that is, in contexts that are personally and relationally relevant. Thus, we would predict cultural differences not only in experience (appraisal of the situation, action readiness) but also in expressive behavior, autonomic and central nervous system changes, and instrumental or relational behavior. Toward the end of this chapter, we argue that, so far, comparative cultural research on these latter aspects of emotion has largely failed to appreciate the ways in which cultural models materialize in emotions due to a lack of consideration of the relevant cultural contexts. Thus, the research paradigms used to study cross-cultural variation in behavior and nervous system activity were not designed to find cultural differences. Because culture-sensitive research can primarily be found in the domain of *emotional experience*, this is the prime topic of this chapter.

Constituents of Emotional Experience

First, consistent with many current theories of emotions, we treat emotional experience as having content that can be meaningfully analyzed (Barrett, 2006; Barrett, Mesquita, Ochsner, & Gross, 2007; Ellsworth & Scherer, 2003; Frijda, 1986, 2006; Frijda, Kuipers, & Terschure, 1989; Scherer, 1984). In this chapter, the focus is on those aspects of emotional experience that most directly implicate the relationship of an individual with his or her context: appraisals of the situation and action readiness. We thus assume that the meaning represented by these facets of emotion constitutes the core of emotional experience (for similar views see Barrett, 2006; Clore & Ortony, 2000; Frijda, 2006). Importantly, the meaning of the situation and the projected action and goal fulfillment (i.e., action readiness) are considered central parts of the emotional experience itself. This is in contrast to many other theories of emotion that consider them peripheral to the actual emotion (e.g., Levenson et al., Chapter 32, this volume).

Focal, Normative, or Ideal Representations of Emotions

Emotional life in a culture is more than the added emotional responses that may be observed or reported. People in many cultures show unique regularities in the frequencies of certain responses that are better understood when one considers the focal, normative, and ideal representations of emotions in those cultures. The unique shapes of people's emotional lives in different cultures are, among other factors, motivated by the central themes of cultural models (Mesquita & Ellsworth, 2001; Mesquita & Frijda, 1992), ideal affect (Tsai, Knutson, & Fung, 2006), and what anthropologists have referred to as emotional style (Middleton, 1989) or *ethos* (Schieffelin, 1985, pp. 172–173):

Ethos refers to the dominant emotional emphases, attitudes, and modes of expression of a culture as a whole. . . . The concept of ethos has generally been used as a descriptive ethnographic characterization. However, to the extent that individuals regularly exhibit attitudes and moods characterized by the ethos, that ethos can be considered expressively normative. That is, it is culturally expected that a person feel a certain way and adopt a certain affective posture and expressive style in relation to particular events. . . . A culture's ethos is thus not only a characterization of a style of feeling and behavior but also a model for it.

Our second mission in this chapter is to describe how focal, normative, and ideal emotional representations are parts of the cultural models.

OVERVIEW OF THE REST OF THE CHAPTER

Our approach builds on the notion that emotional experience is always saturated with meaning, and that meaning is cultural (Bruner, 1986). Though emotions may and often do involve hardwired processes, the meanings at the core of emotions are particularized to culture.

In the sections that follow, we first aim to render the cultural shaping of emotion constituents transparent, indicating how emotional constituents themselves fit and contribute to the cultural models. We then focus on systematic cultural differences in the focal, normative, and ideal representations of emotions, and what seem to be resultant regularities in emotional patterns.

CULTURAL DIFFERENCES IN THE CONSTITUENTS OF EMOTIONAL EXPERIENCE

When people in different cultures say they feel “angry,” they may refer to quite different experiences. In this section, we start from the assumption that emotional experience can be described as an aggregate of the constituent meanings (Barrett et al., 2007; Frijda, 2006). We furthermore assume that the culturally most prevalent emotional experiences systematically reflect the cultural models of self and relating, and can thus be studied in a theory driven and meaningful way (Mesquita, 2003; Mesquita & Markus, 2004). In the following sections we discuss cultural differences in appraisal and in action readiness changes.

Appraisal

Appraisals are “psychological representations of emotional significance” (Clore & Ortony, 2000, p. 32). Cultural models transpire in appraisals. Thus, independent appraisals consist of the perceived impact of the situation for individual goals, whereas interdependent appraisals likely specify the impact of the situation on relational goals. Naturally, cultural models vary on more than just the dimension of individual versus relational meaning. More intricate descriptions of cultural models tend to provide better contexts for understanding the cultural specificity of appraisals.

What Is the Emotional Situation?

The appraisal of an emotional situation is rooted in what the relevant stimulus is judged to be. Some have called this the appraisal dimension of “interest”: What is the situation that might be relevant for me (Ellsworth, personal communication, 2004; Frijda, 1986)? There is some evidence that the parsing of reality is characterized by the pertinent cultural model.

An experience sampling study by Oishi, Diener, Scollon, and Biswas-Diener (2004) found that whereas the social context affected emotional experience in interdependent cultures, it did not do so in independent cultural contexts. Thus, according to this study, emotions were experienced no differently in situations with or without others in independent contexts, but emotional experiences in interdependent contexts were different depending on

the presence of certain others. The way reality was parsed appeared to be different.

In this study, American college students in the Midwest (mostly European Americans), Hispanic students living in California, Japanese college students in Japan, and Indian college students in India completed a mood questionnaire five times a day. The mood questionnaires consisted of a positive and a negative affect scale. Each time students filled out the mood questionnaire, they also indicated the nature of the situation in terms of six options: whether they were alone, with a friend, with a classmate/coworker, with a romantic partner, with a stranger, or with family. Though cross-situational consistency of both positive and negative affect was prevalent across all four cultures, affect was more dependent on the type of situation in interdependent (Hispanic, Japanese) than in independent (non-Hispanic American) cultures.² More specifically, in the Hispanic and Japanese groups, the mean level of positive affect experienced in a family context was not significantly correlated with positive affect in a number of other social situations. In contrast, positive affect among European Americans was consistent across all six emotional situations. For negative affect, Hispanics were the only group to report different mean levels of affect in family contexts than for the other social situations; negative affect in the other three cultural groups was consistent across situations. Oishi et al. (2004) concluded that, particularly in the case of positive affect, the precise nature of the social context was more consequential for the feelings of the interdependent cultural groups in this study than for the independent group.

Oishi and colleagues (2004) also calculated differences in the degree of *overall* within-person variability in affective experiences across situations by computing a standard deviation of mean positive and negative affect across six situations for each individual. In general, the standard deviation was larger for positive than for negative affect, meaning that the influence of the type of situation was larger for positive than for negative emotion. Furthermore, there were clear cultural differences in the direction one would expect. For positive emotions, the mean within-individual cross-situational variation was higher among Japanese and Hispanic respondents than among Americans, whereas for negative emotions, all

three interdependent cultural groups had a higher mean within-individual cross-situational variation than Americans. Therefore, within individuals the level of positive and negative emotion was more affected by the specific social situations in interdependent than in independent culture, consistent with the relational orientation prevalent in interdependent cultures. It should be noted that these differences in *within*-person cross-situational variation were found against the backdrop of robust universal *between*-person effects. The similarity in between-person effects meant that across cultures, a person's mean affect was predictive of his or her affect in different situations.

A study on emotional perception supports the idea that the parsing of reality varies according to the different cultural models. In this study, respondents reported on someone else's emotional experience rather than their own. Japanese and European American individuals were presented with cartoon stimuli depicting a central person who expressed anger, sadness, or happiness, surrounded by four other people whose facial expressions varied independently from that of the central person (Masuda, Ellsworth, Mesquita, Leu, & Veerdonk, 2005). Respondents were asked to rate the central person's emotional experience. The results strongly suggest that the situation of interest is constructed as the relationship among the Japanese, but not among European Americans. Consistent with an independent model, Americans judged the central person's emotional experience by his expression alone, disregarding the emotions of the surrounding people. Consistent with an interdependent model, however, the Japanese participants considered the emotions of all the people in the picture.

Therefore, when assessing the central person's emotional experience, Japanese participants were affected by the emotional expressions of others in the situation, not just by the expression of the central person. For example, anger ratings of an angry person were up if other people in the situation were angry as well, compared to a situation in which the other people were not angry. In the Japanese group, the emotions of the people in the background influenced what emotion was perceived in the central person. Japanese respondents recognized more happiness in an angry central person, when he was surrounded by happy people. Therefore, the meaning of the situation

in a Japanese interdependent context is to be found in what is going on with *everybody* in the social interaction.

In a subsequent experiment, Masuda and his colleagues (2005) measured eye movement during the same emotion judgment task, and found that whereas Americans attended mostly to the central person, Japanese started to divide their attention between the central person and the surrounding people after the first second. Thus, the reality perceived or attended to seemed to differ very early on in the task. Independent models are associated with perception of a bounded individual, whereas interdependent models guide and afford a relational perception.

Similar results were obtained by Tsang and Wu (2005), who had Taiwanese students rate the happiness of schematic representations of either smiley or sad faces. The central face was surrounded by four other faces that were also either smiley or sad, and varied independently of the expression of the central face. Consistent with interdependent Taiwanese models, the central face was rated higher on happiness when surrounded by happy than by sad faces. Tsang and Wu used two different shapes for the surrounding faces. These faces were either round like the central face, or egg-shaped to differ slightly from the central face. The effect of the emotion of the surrounding faces on the judgment of the central face was moderated by the degree of similarity between the central and the surrounding faces. Surrounding faces that were similar to the central face had a significantly larger effect on happiness ratings than surrounding faces that were different. On the basis of these results one might infer that in interdependent contexts, other people become part of the emotion stimulus to the extent that they are seen as related to the individual or belonging to the same group.

Cultural models thus afford certain perceptions of emotional stimuli. Whereas interdependent emotional experience is focused on the group, independent emotional experience is associated with attention to the individual. These different perceptions of reality are the basis of different types of emotional experience. Future research should explore the divergent implications of these types of emotional experience in terms of their cognitive and behavioral consequences. Cognitive and behavioral implications would also provide stronger validation of the position taken here.

What Is the Perspective on the Situation?

Cultural models appear to be reflected in the emotional experience in yet another way, namely, by the perspective taken on emotional events. Whereas people in independent contexts view emotional situations mainly from their own perspective (called an inside-out perspective; Hamaguchi, 1985), people in interdependent contexts assess the emotional meaning from the perspective of other people, either particular other people or a generalized other (cf. Mead, 1934). The latter perspective has been called outside-in (Hamaguchi, 1985).

Several studies suggest that the perspective of others is experienced as part of the situational appraisal in interdependent contexts, but much less so in independent contexts. For example, Mesquita (2001) compared emotions in independent and interdependent cultural contexts in the Netherlands. Respondents reported three types of emotional events from their past: positive, offensive, and immoral situations. Surinamese and Turkish minorities in the Netherlands, the interdependent cultural groups, reported more awareness of how the situation would be perceived by others than did respondents from the Dutch independent majority group. The Turkish and Surinamese groups regarded the emotional meanings of the situation as more "obvious" than did the Dutch; they assumed that others would interpret, feel, and act in a similar manner in the target situation. The meaning of emotional situations in interdependent contexts was perceived to be a feature of the world that could only be perceived similarly by others, whereas the meaning in the independent context was construed inside-out. To the extent that people perceived the appraisal of an event or a person to be shared by others, it was more likely to turn into a long-term belief (Mesquita, 1993). For example, in the Surinamese and Turkish groups, more often than in the Dutch group, an offense by a friend led to the lasting belief that the friend was unworthy of one's friendship. Others' perspectives were experienced as convergent with one's own, and provided the appraisal with some force and justification.

Similarly, in a study comparing American and Japanese respondents, both university students and a community sample, the interdependent Japanese respondents reported more appraisals that reflected an awareness of the

meaning of the situation to others than did the American respondents (Mesquita et al., 2005). However, in contrast to the interdependent groups in the Netherlands, Japanese respondents represented the perspective of others as different from their own. Respondents in this study reported their emotional experience and behavior in three types of situations from their past—offense, humiliation, or being valued. Respondents' emotion narratives were recorded and later coded. In the negative situations in particular, Japanese respondents considered the meaning of the events for other people as it differed from their own. For example, more than 40% of the Japanese, versus none of the Americans, explained the situation from the perspective of a third person or a generalized other, an appraisal that can be seen to reflect an outside-in perspective. The Japanese consideration of the divergent perspective of others may be responsible for the fact that the most frequently reported response to offense was doing nothing, as opposed to the assertiveness and aggression reported by European Americans. The awareness of the perspective of another person may make one less likely to act against the offender.

Evidence for an outside-in perspective in interdependent cultures and an inside-out perspective in independent cultures also emerges from a study among Canadians of Western and Eastern descent on the attribution of emotional experience to others (Cohen & Gunz, 2002). Respondents recalled an emotional event from the past that had induced a given emotion. Emotions were selected to form relational pairs, such that when one person has one emotion, a relating person may be expected to have the complementary emotion (e.g., sympathy–sadness). After one emotion was primed, respondents rated a set of ambiguous emotional faces. Because it is important in interdependent contexts to see one's own emotions from the perspective of another person, Easterners were expected to recognize more of the complementary emotion in the faces presented. Westerners, lacking the perspective of a complementary emotion, were expected to rely on their own experience when reading other people's ambiguous faces. The results confirmed these predictions. For example, when sympathy was primed, Easterners perceived higher levels of the complementary emotion of sadness. On the other hand, Westerners perceived the faces as more similar to the emotions they had just de-

scribed. When primed with sympathy, Westerners perceived more sympathy in the faces. Canadian respondents of Eastern descent (interdependent cultural model) showed an implicit awareness of others' perspective on the respondents' emotions, whereas Westerners lacked such perspective.

Relational Appraisal

The social and relational implications of emotional events are more readily emphasized in interdependent than in independent cultural contexts. First, the status of relationships with others tends to be more central in interdependent than in independent appraisal. Kitayama and his colleagues demonstrated that emotional appraisals of the situation as one of interpersonal engagement were more prevalent in Japanese than in North American student populations (Kitayama, Markus, & Kurokawa, 2000; Kitayama et al., 2006). In a pilot study, Kitayama and Markus added indigenous Japanese words "that presuppose the presence of others" (cited in Markus & Kitayama, 1991, p. 238) to the standard list of English emotion words, and gave the compiled list of emotions to Japanese students, who provided similarity ratings of all possible pairs of emotions. In addition to the pleasantness and arousal dimensions commonly found in similarity rating studies using standard Western emotion words, the Japanese ratings yielded a dimension of interpersonal engagement, ranging from socially disengaged emotions such as pride and anger at one pole, to socially engaged emotions such as shame and feelings of connection with someone (*fureai*) at the other pole.

In subsequent experience sampling studies, both positive and negative engaged emotions were more frequent than disengaged emotions in Japanese contexts, whereas the reverse was true in independent European American contexts (Kitayama et al., 2006). In these studies, Japanese and European American students rated both engaged and disengaged emotions in a daily experience sampling study, and in response to 22 very diverse emotional events. The largest differences appeared for the disengaged emotions. Whereas Japanese and European American students similarly appraised situations with regard to their implications for relational engagement, European American students reported significantly higher levels of disengaged emotions for both the positive and

the negative situations. These differences in disengaged emotions thus resulted in a relatively stronger role for engaged appraisals in the Japanese context.

Convergent evidence comes from another experience sampling study with European American and two groups of Japanese college students, one in the United States, and the other living in Japan (Mesquita & Karasawa, 2002). In this study, respondents reported their most recent emotion every 3 hours throughout the week and rated the eliciting situation with respect to pleasantness, as well as a number of appraisal dimensions that represented independent appraisals (such as self-esteem and control) and interdependent appraisals (such as closeness and face loss), and indicated how pleasant or unpleasant the situation was. Pleasantness in the two Japanese groups was better predicted by the interdependent than by the independent appraisals. In the European American group, pleasantness was predicted no less by independent than by interdependent appraisals.

That pleasantness was predicted no better by independent than by interdependent appraisals should perhaps not be surprising. In European American contexts “good feelings are associated with participating in some form of mutually approving relationship” (Kitayama & Markus, 2000, p. 135). Thus, relational appraisals may be highest when the relationship contributes to feelings of self-efficacy and self-esteem. Consistently, independent and interdependent appraisals in the experience sampling study just described were highly correlated.

On the other hand, independent appraisals in the Japanese groups were uncorrelated with interdependent appraisals. In the Japanese groups, feeling good about the independent aspects of self is unrelated to having a positive bond with others, and the latter, rather than the former, predicts whether one is feeling good (Kitayama & Markus, 2000).

Respect and status were salient social dimensions for the Surinamese and Turkish respondents in the Dutch study reported earlier (Mesquita, 2001). Positive events were described in the interdependent contexts as raising one’s status and respectability, and that of one’s family or ingroup, whereas negative events were described as threatening or detrimental to status and respectability; this was hardly the case for the Dutch independent con-

text. Thus, the interdependent focus on the implications of an emotional event for one’s social worth was suggested by this study as well, despite the fact that it included very different cultural groups.

An emphasis on the social consequences of emotional events can also be found in cultures where many events derive meaning from their relevance to honor. Honor in this sense is based on a person’s strength and power over others. Honor situates people socially and determines their right to precedence (Abu-Lughod, 1986; Cohen, 1996; Cohen & Nisbett, 1994, 1997; Cohen, Nisbett, Bowdle, & Schwarz, 1996; Peristiany, 1966). Thus, emotional appraisals in honor-based cultures tend to be fully grounded in a consideration of the social position and social relationships of the individual. Social position is sometimes negotiable (Cohen et al., 1996), but it can also be perceived a result of the natural order of things, such as the lower status (and thus higher vulnerability) of women compared to men (Abu-Lughod, 1986).

More evidence for the different concerns that are central in emotional experience comes from a priming study (Chentsova-Dutton & Tsai, 2005). Asian American and European American college students were randomly assigned to either the individual self-focus condition, in which they wrote “about themselves and the conditions in their own life,” or the relational self-focus condition, in which they wrote “about family members and events in their life.” After the writing task, respondents watched either a sad film clip or an amusing one. European American respondents watching the amusing clip reported higher-intensity positive emotions and smiled more after the individual focus than respondents in the relational self-focus condition. Conversely, Asian American respondents reported and showed more positive feelings after the relational focus condition than after the individual self-focus condition. One interpretation of this finding is that emotional experience is commonly associated with independent concerns in independent contexts, and with interdependent, relational concerns in interdependent cultural contexts. Once the relevant concerns are activated, the emotions become more intense. A caveat to strong interpretations of this finding is the lack of significant interaction between culture and focus of condition after respondents watched sad film clips.

Control Appraisal

Evidence for the unique shaping of appraisals in independent contexts comes from the research on agency and personal control (Ellsworth & Scherer, 2003; Frijda et al., 1989; Weiner, 1982, 1986). Whereas the tendency to explain outcomes appears to be universal, the tendency to attribute important outcomes to one's own individual agency seems to more specific to independent contexts. This type of agency is a key aspect of independent cultural models, American ones in particular, where success through independent, personal accomplishment is central (Markus & Kitayama, 1991).

Participants in a number of questionnaire studies were asked to remember an instance of a given emotion, describe the situation, then rate the situation on a number of appraisal scales provided by the researchers (Mesquita & Ellsworth, 2001). These appraisal studies yielded impressive evidence for cross-cultural similarities in appraisal, but agency was one of the dimensions on which appraisal profiles tended to vary across cultures. Whereas individual agency was an important dimension of appraisal in the original studies with Western samples (Frijda et al., 1989; Scherer, 1984; Smith & Ellsworth, 1985), it was much less so for non-Western samples (Matsumoto, Kudoh, Scherer, & Wallbott, 1988; Mauro, Sato, & Tucker, 1992; Scherer, 1997). For example, Matsumoto and colleagues (1988), comparing Japanese and American students, found that agency—an important descriptive dimension of emotion for American students—was often considered “not applicable” by Japanese respondents.

Furthermore, agency appears to be an important predictor of pleasantness or well-being in independent but not in interdependent contexts. In American contexts, emotions of agency, such as pride, were found to predict general feelings of well-being. In contrast, emotions of relatedness rather than emotions of agency predicted well-being in Japanese contexts (Kitayama et al., 2000, 2006; Mesquita & Karasawa, 2002). These results may be related to the cross-cultural finding outside the emotion literature, demonstrating that European American children were most motivated in a task they had selected for themselves, whereas Asian American children preferred tasks chosen by their mother or their friends

(Iyengar & Lepper, 1999). The positive connotation of individual agency may thus be specific to independent cultural models.

The differences in salient appraisals reflect different cultural models. Salient independent appraisals consist of individual agency and control; conversely, interdependent appraisals are about a number of different relational meanings of the situation.

Action Readiness and Behavior

Emotions tend to involve behavior, or at least the intention of behavior, aimed at changing the relationship between the self and others. We distinguish conceptually between behavioral goals (action readiness) and behavioral means (the actual behavior), despite the fuzzy empirical distinction. Behavioral goals—or inclinations to behavior—have been termed as *action readiness* (Frijda, 1986), which is related to appraisal in that it constitutes the tendency or preparedness to deal with the emotional issues as construed; actual behavior is the executed effort to do the same. Action readiness and behavior, importantly, are afforded and shaped by the meaning of the event as constructed, and in this way reflect the cultural model.

Action readiness and behavior themselves represent the normative and descriptive relationships between an individual and his or her social context. Both the actual and the most desirable behavioral means to reach the normative relationships between an individual and others constitute the cultural models.

Action Readiness

The few cross-cultural studies that explicitly address cultural differences in action readiness suggest that, in addition to some universal themes in action readiness, there are many cultural differences. A study by Frijda, Markam, Sato, and Wiers (1995) compared the action readiness modes reported by Dutch, Indonesian, and Japanese participants after recalling a given emotional experience. All respondents rated these self-reported instances of emotions on the same action readiness items. Use of stimulus emotion words was the most frequent in recall studies with Dutch and Indonesian respondents. The Japanese words were translations of those concepts.

For each culture, factor analyses on the action readiness items suggested that five (of the

six to nine) factors in each of the three cultural groups were similar: *moving away*, *moving toward*, *moving against*, *want help*, and *submission*. These factors can be interpreted as general themes of behavior and explain a substantial part of the differentiation between emotion words. Right away, it should be noted that not *all* factors were universal, and that some of the culture-specific factors were easily understood from the specific cultural models. Consistent with the independent motive of control, for example, *in command* was a unique factor of behavior in the Dutch group. And consistent with the concern for avoidance of disruption, one factor in the Japanese group consisted of disengagement (*apathy*, *disinterest*), an accepted way to give expression to negative feelings in this culture (Karasawa, personal communication, July 2004).

Moreover, the relative importance of the five shared themes of action readiness differed across cultures. Cultural models of the three groups offer plausible explanations for these variations across cultures. The dimensions of *moving away* and *moving against* were more important in discriminating between emotion words in Dutch than in either of the other languages. Thus, *moving away* and *moving against* were defining elements of Dutch emotional experience. The Dutch cultural model of seeking independence, if necessary through opposition (as a way of expressing oneself; Stephenson, 1989; Van der Horst, 1996), may explain the significance of the action readiness modes of *moving away* and *moving against* in the Dutch emotional experience. On the other hand, the dimensions of *moving toward* and *submission* allowed more differentiation between different emotional experiences in Indonesian and Japanese than in the Dutch contexts. These dimensions fit with the goals of relational harmony in the cultural models of these Asian groups (Markus et al., 1997); moving toward others may reduce social distance, and submitting may make one acceptable to another person.

Different behavioral goals can sometimes be inferred, if cultural differences in the rate of behavior are meaningful within different cultural models. For example, several studies have yielded cultural differences in the rate of general bodily or somatic activity, which can be conceived as a way to occupy space in the relationship. In questionnaire research, Japanese respondents reported many fewer hand and

arm gestures and whole-body activity than did Americans in situations of anger, sadness, fear, and happiness (Scherer, Matsumoto, Wallbott, & Kudoh, 1988). The difference can be understood as fitting an emphasis on the relationship among the Japanese, and on the individual among American respondents. Especially interesting is that the cultures did not differ in the reported control of these emotions. The lower frequency of active somatic behaviors among the Japanese is more likely the result of a lower level of initially generated activity than of post hoc regulation.

These self-report data converge with actual measurements of general somatic behavior, or the amount of movement in any direction. Tsai and Levenson (1997) found that Chinese American couples who discussed a conflict area in their relationship displayed less general somatic activity than did European American couples. General somatic activity was one of the few physical response measures on which the two cultural groups differed.

There is some indication that the expression of high-activation happiness, another emotion accompanied by expansive behavior, is more common in independent cultures. Tsai, Chentsova-Dutton, Friere-Bebeau, and Przymus (2002) asked European Americans and Hmong Americans to relive high-intensity emotional episodes of a number of emotions, including happiness. The main difference in recorded facial behavior and physiological reactivity was that European Americans had many more social smiles during their recall of intense happy events than did Hmong Americans. This was the case despite the fact that the reported emotional feeling and physiological activity did not differ between cultural groups. Furthermore, highly acculturated Hmong Americans showed significantly more social smiles than less acculturated Hmong Americans, suggesting that adoption of American culture is associated with a higher frequency of social smiles during happiness. European Americans (and, by extension, highly acculturated Hmong Americans) may use their social smiles to convey to others that they experience the socially desirable emotion of happiness, which portrays the individual as independent and successful.

On the other hand, high-activation happiness expressions seem to be rarer in cultures that place an emphasis on harmony in relationships (Lutz, 1987). Expressions of elated happiness are seen as potentially disruptive, be-

cause they may painfully contrast with the emotional state of others or may be seen to indicate the plausibility of an individual challenging social obligations and evading responsibilities (Lutz, 1987; Karasawa, personal communication, July 2004). Happiness may have had that same connotation for the Hmong Americans in the study by Tsai and colleagues (2002).

Emotional Behavior Consistent with Situational Meaning

Differences in behavioral intent can sometimes be understood from the differences in appraisal or the meaning of the eliciting event. For example, the behavioral goals of shame differ according to different constructions of the shame stimulus (Mesquita & Karasawa, 2004). Whereas shame in independent Western contexts tends to be linked to withdrawal or the desire to disappear from view (Frijda et al., 1989), shame in interdependent East Asian contexts is associated with attempts to restore relationships. In the latter contexts, it is often accompanied by declarations of shame, public apologies, and public weeping to parents or the nation, and by both public and private declarations of intention to change one's unworthy actions and identity (Mascolo, Fischer, & Li, 2003).

The differences in the behavioral concomitants of shame can be understood from the meanings associated with shame. Shame in independent Western contexts has been associated with an appraisal that the event is incongruent with one's identity goals, and that it is caused by discrepancy with one's own stable characteristics (Tracy & Robins, 2004). Thus, shame occurs when an event conflicts with who one wants to be, as is the case when a student fails an exam, attributing it to lack of ability. On the other hand, shame in interdependent East Asian cultures appears to be the assessment that what happens is incongruent with *relationship goals*—one's obligations to others, to one's parents, to the nation, and so forth—and that it brings dishonor on the people or groups to which one belongs. Of course, even in a Western context the failure to meet one's identity goals derives its significance from the potential for social rejection (Baldwin & Baccus, 2004), which ultimately is a relational concern. Yet the relationship that elicits this type of shame is between relatively auton-

omous individuals, each responsible for his or her own success. It is very different from the focus of the relationship itself that appears to be at the center of shame in East Asian contexts. Consistently, whereas shame in Western cultures focuses on internal flaws, shame in East Asian cultures seems to be centered primarily on negative social outcomes, regardless of whether the individual was responsible for those outcomes (Crystal, Parrott, Okazaki, & Watanabe, 2001).

Shame in East Asian cultures is thus an attempt to repair the relational harm done rather than the expression of ultimate failure it is in the West. The answers to East Asian shame are self-improvement and the public sharing of shame, both ways to reassert oneself as a member of the social group to which one belongs. These behavioral goals are completely different from the common, Western action readiness of shame, wanting to disappear from others' view, which is in turn an appropriate response to ultimate, unchangeable failure and the high potential for rejection.

Similar differences in shame reactions were indeed found in a questionnaire study on shame among salespersons in the Netherlands and the Philippines (Bagozzi, Verbeke, & Gavino, 2003). Salespeople in both cultures rated how they would respond in situations in which statements or actions by customers caused them to feel shame. Salespeople in a Dutch independent context were expected to interpret the shaming by a customer as a sign that their independent self-goals were negatively evaluated, and that they were thus denigrated and ridiculed. Philippine salespeople, on the other hand, were predicted to be concerned about their social identity and the relationship with the customer. Consistent with their projected construal of the situation as harmful to the personal self, Dutch salespeople reported that their shame would lead them to protect themselves from further denigration (i.e., withdraw). On the other hand, Philippine shame was not associated with protective action.

These culturally different responses associated with shame in turn predicted differential performance outcomes, again, as reported. For the Dutch salespeople, protective action—highly related to shame—was *negatively* associated with sales volume, communication effectiveness, and relationship building. Thus, within the Dutch sales business, shame is a counterproductive emotion. On the other

hand, shame in the Philippine sales business was positively associated with “adaptive resources,” comprising relationship building, civic virtue, and courtesy, apparently in an attempt to fix the relationship with the customer. For Philippine salespeople, shame appears to be a productive emotion.³

Another study illustrating the way behavioral goals rest on the cultural understanding of emotional situations compared the behaviors of Northern and Southern men in the United States in an experimental setting in which they were offended (Cohen, Vandello, Puente, & Rantilla, 1999). Offense in Southern cultural settings challenges one’s honor, especially when it is intentional, but in Northern cultural settings, it does not (Cohen et al., 1996). For this reason, Southerners avoid any perception of offense by following an elaborate system of politeness rules. This leaves Southerners inexperienced with subtle hostility when it occurs. In contrast, Northern discourse prepares Northerners well for these small hostilities and rudeness. Consistently, Southerners took longer than Northerners to respond angrily (as measured by ratings of facial expressions and the risk of physical or verbal confrontation) to an annoying confederate in an experiment who interfered with task completion. On the other hand, once the annoying behavior had angered the Southerners, they expressed more intense anger and were judged more ready to engage in physical or verbal confrontation. One interpretation of these findings is that once the offense is taken seriously, Southerners *must* reciprocate to defend their honor and even the score.

In the experiment just discussed, the confederate offered his apologies at the end of his annoyances. Apologies were more readily accepted by Northerners who had remained calm, and by Southerners who had become angry than by angry Northerners and calm Southerners. Thus, for Northerners it was easier to forgive when they had not worked themselves up first, but for Southerners it was easier to forgive when the score was even. Finally, 6 months after the experiment was over, Southerners who had remained calm and Northerners who had become angry were much better at recognizing the confederate’s picture than were Southerners who had been angry and Northerners who had remained calm. The emotional experience was apparently more memorable for Southerners who had not evened the score

and for Northerners who had violated their cultural script of remaining calm. Both the behaviors observed and the consequences of these behaviors could be understood and predicted from the meaning of the eliciting situation.

Emotional Behavior Tailored to the Cultural Context

There is also some evidence for cultural differences in the specific behaviors people use to realize similar behavioral goals. The questionnaire study of action readiness among Dutch, Indonesian, and Japanese groups is a case in point. For example, the behavioral goal of submission was instantiated by *comply*, *depend*, and *apathy* modes in the Dutch group. In the Indonesian group, it was instantiated by those same three action readiness modes, plus modes that reflected a lack of control over one’s actions (*inhibited*, *helpless*, *blocked*, and, negatively, *in command*). In Japan, submission comprised action readiness modes of dependence (*depend* and *comply*), lack of control (*blocked*, *helpless*), and social engagement (*make up for it*, *tenderness*). The specific action readiness modes serving the overarching behavioral goal—submission, in this case—appear to be cross-culturally different in ways consistent with cultural models. In the independent Dutch context, submission is restricted to those contexts in which one is dependent, or without the energy to resist. In interdependent cultures, not taking control may be a sufficient condition for others to take the lead. Therefore, to feel blocked or helpless may automatically mean to submit. Furthermore, consistent with the Japanese model of relationship (e.g., Lebra, 1994), social engagement in Japan may in fact mean being able and willing to yield to other people.

More evidence that behavioral goals fit the meaning of emotional situations comes from the narrative study with North Americans and Japanese, reported earlier (Mesquita et al., 2005). Cultural differences in behavioral goals fit with the models of self and relating. The most prevalent response categories reported by European American respondents were to be *assertive* or *aggressive*, both behaviors that underline the boundaries between different people. On the other hand, the most frequent action readiness or behavior reported in the Japanese group, *doing nothing*, serves to maintain the relationship, or at least not disturb it in any obvious way. These results are unlikely to be produced by differences in the American

and Japanese concrete offense situations, because similar results for appraisal and action readiness differences were obtained in a controlled study that used vignettes (Mesquita et al., 2005, Study 2).

Similarly, in comparative work with Dutch, Surinamese, and Turkish respondents in the Netherlands, Mesquita (1993) found that aggressive goals tend to be sought after in ways that make sense within the unique cultural models. For example, Surinamese and Turkish respondents reported a higher tendency to show indifference in situations in which they had been harmed by another person. The high value attached to relatedness in those cultures compared to that among the Dutch turns “indifference”—the denial of engagement—into an effective act of aggression.

Ethnographic work suggests that culture-specific behaviors sometimes are chosen to serve emotional goals in a way that is not disruptive of the cultural models (Mesquita & Frijda, 1992). For example, according to the ethnographers, the Balinese reaction to frightening events is to fall asleep (Bateson & Mead, 1942). This behavior can be understood as a culture-specific instantiation of a more general goal of fear: avoidance. Falling asleep satisfies—at least subjectively—the goal of reducing one’s exposure to the threat, while avoiding the emotional disruption that other fear responses are felt to cause. Therefore, falling asleep can be considered a culturally effective way to accomplish the goal of avoidance (or *moving away*).

Withdrawal may have different meanings depending on the specific cultural and situational context. *Satru* in Javanese contexts refers to an institutionalized pattern of avoidance, in which individuals in conflict refuse to speak or interact with one another (H. Geertz, 1961). Given the Javanese ideal of social harmony (*rukun*) that requires the concealment of all dissonant aspects, *satru* “is an excellent mechanism for the adjustment of hostility in a society that plays down violence and the expression of real feelings, since it allows for the avoidance of an outbreak of rage while still permitting significant expression of it” (pp. 117–118). In this case, therefore, withdrawal serves feelings of hostility in a context that does not allow for straightforward hostility.

In summary, the meaning, and, therefore, the appropriateness and effectiveness of certain behaviors in specific contexts differ according to

cultural models. Note that a relational or interdependent orientation does not always lead to reaching out and being sociable. Shame in East Asian cultures has been described as leading more often to approach than has shame in Western contexts. However, the Balinese and Javanese examples suggest that the direction of emotional behavior in situations of potential conflict tends to be just the opposite, namely, withdrawal. Conversely, shame in Western contexts tends to be associated with withdrawal, whereas hostility is paired to antagonistic behavior. Thus, the type of emotional behavior in independent and interdependent contexts, rather than being consistently in one direction, follows from the meaning of the behavior, given a certain cultural context.

Evaluating the Importance of Cultural Differences in Meaning

How important are the differences in emotions? Are they superficial variations on a universal theme, or are they essential to emotional experience? We contend that *if* one wants to understand or predict what people in different cultures feel and do during emotional episodes, the culture-specific meanings of emotions are indispensable. It might often be possible to make the cultural differences in emotion dissipate by describing the phenomena at a sufficiently high level of abstraction (Mesquita, Frijda, & Scherer, 1997), but doing so takes away from the understanding of the psychological phenomena (Mesquita & Frijda, 1992; Mesquita et al., 1997). It is possible, for example, to describe the prevalence of relational appraisals in interdependent cultures as an alternative route to positive self-feelings? People in interdependent cultures might determine whether they feel good about themselves by keeping tabs on their social value, in the same way that people in independent cultural contexts monitor their personal value or self-esteem. Conversely, one could argue that self-esteem is the Western manifestation of the universal need to belong (Leary & Baumeister, 2000) and, given this, people across cultures appraise their chances of being accepted or rejected by others. How precisely one’s social value is computed—whether by self-esteem, honor, or level of fitting in—may be different across cultures. However, the appraisal of social value can be deemed universal.

We do not deny that it is possible in many

cases to read these universal themes into the observed cultural differences, and to do so may be useful, depending on the research question of interest. However, an accurate representation of the actual emotional experience in different cultures requires understanding of the culturally embedded meanings of emotion-eliciting events (Mesquita et al., 1997). Cultural models constitute the content of feelings, and render emotional acts comprehensible and predictable.

For example, it is important to understand that insults are conceived of as honor violations in the South of the United States. This interpretation explains why, in response to insults, Southerners show more anger and aggressive responses than do Northerners, who do not have an honor culture. This interpretation also explains why Southerners are likely to bear less resentment than Northerners after they have expressed their anger (the score is evened; strength is being exhibited; Cohen et al., 1999). To understand the emotional experience and emotional responses, it is thus important to consider the cultural models that lend meaning to the antecedent event.

Similarly, it is important to know that Westerners are more likely to attribute personal agency to emotional events, because agency appraisals have important correlates in the course and experience of emotions. For example, blaming someone else for an offense—the prevalent American anger appraisal—rather than assuming that these things happen or that another person probably had a good reason—the common Japanese appraisal—has very different implications both for emotional experience and behavior (Mesquita et al., 2005). Blaming the other person tends to result in assertion and aggression. Sympathizing with the offender, on the other hand, leads to decreased emotionality and, in many cases, to doing nothing at all.

The question here is not whether it is *possible* to describe behavior without reference to culturally rich meanings, but whether such description is relevant given the question of interest. We contend that in most cases highly abstract descriptions of people's behavior would capture neither the precise intentions of the behavior nor their subjective experience. If one is to predict or understand what people will do, or want to do, in actual emotional contexts, one has to take into account the meaning that these behaviors have in these contexts, beyond just moving in a certain direction. It is impor-

tant to know whether moving away is an expression of hostility, as is the case for Javanese (H. Geertz, 1961), or an escape from the exposure to others, as is the case in Western shame (Bagozzi et al., 2003; Frijda et al., 1989). The resulting social and behavioral consequences, as well as the experience of this behavior, are likely to be very different depending on its meanings.

NORMATIVE OR IDEAL REPRESENTATIONS OF EMOTION

Emotional life in a culture is more than the sum of single emotional responses, such as those described in the previous section. Different patterns of emotion can be described in terms of the frequency of individual emotional responses, but they become easier to understand when considering the focal, normative, and ideal representations of emotions in those cultures. This discussion turns to an examination of prevalent or prescribed emotion norms and goals, because they affect the evaluation of certain emotional states as “good” or “bad,” and also determine what people seek out or avoid.

Focal Emotions and Emotion Regulation

Cultures have emotions they “admire and despise” (Mesquita & Ellsworth, 2001). These so-called focal emotions are central in social discourse. Admired emotions tend to be those reinforcing the cultural model, whereas despised emotions violate the model (Mesquita, 2003). Focal emotions, whether positive or negative, are importantly motivating. In ways that we illustrate shortly, admired emotions are sought out and occur frequently, and despised emotions are avoided and occur rarely (cf. Eid & Diener, 2001; Fessler, 2004; Mesquita & Frijda, 1992).

An example of an admired, therefore focal, emotion is happiness in American contexts. Excited happiness seems to be sought out and cherished in many different ways (D'Andrade, 1984). First, many occasions are created that bring about happiness, such as compliments, celebrations, and awards (Kitayama, Karasawa, Heine, Lehman, & Markus, 1999, cited in Heine, Lehman, Markus, & Kitayama, 1999; Miller, Fung, & Mintz, 1996). Second, Americans tend to seek out those occasions that make them feel unique and, therefore,

happy (Elliott, Chirkov, Kim, & Sheldon, 2001; Kim, 2001). Third, when encountering positive events, Americans appear to feel better and appraise the event as contributing more to self-esteem than do people from some other cultural contexts, such as the Japanese (Kitayama, Markus, Matsumoto, & Norasakkunkit, 1997; Leu et al., 2007). Fourth, there is some evidence that Americans express their happiness more, or at least signal to others that they are happy (Tsai et al., 2002; Wierzbicka, 1994). Thus, excited happiness, the ultimate emotional goal in the American independent cultural model, motivates and regulates (1) social production of events, (2) individual selection of events, (3) emotional appraisals typical of happiness, and (4) the expression of emotion.

An example of a despised, and thus focal, emotion is anger in many cultures that value harmony and equilibrium of mind, such as the Utku Inuits in Canada (Briggs, 1970). Anger, a very central topic of discourse among the Utku, is always discussed in association with the dangers attached to it. In-group anger is avoided at all cost. Like approach, avoidance of a focal emotion is accomplished at different levels of the generative process of the emotion (Mesquita & Albert, 2007). First, events that would elicit anger are avoided. For example, the aim of normative behavior is to avoid frustrating others or blocking their goals. Second, anger is mostly avoided and discouraged by others, who disapprove of it, show fear, or incite shame. It is unlikely for this reason too that anger would be sought out. Third, Utku Inuits seem to be reluctant to blame another person for a negative event, because blame is an appraisal that is conditional to anger. Blame does not fit the Utku worldview of resignation and acceptance (Solomon, 1978). Finally, Utku Inuits regulate anger expressions, as is clear from the display rules they convey to children. Thus, the focality of anger, the ultimate threat to social harmony which is so central in the Utku cultural model, can be inferred from (1) the suppression of social events that would elicit anger, (2) the relative absence of blame appraisals, and (3) the near-absence of anger expressions.

Ideal Affect

Even when emotions are not focal in this strong sense, the average person's ideal emotions may differ from one culture to the next. Tsai and

colleagues (2006) distinguished between actual and ideal affect, and found cultural differences in ideal affect. Whereas actual affect was measured as the feelings one *typically* feels, ideal affect was measured as the feelings one would *ideally* like to feel (Tsai et al., 2006). Not surprisingly, European Americans, Chinese Americans, and Chinese in Hong Kong in the Tsai et al. study indicated that, ideally, they would like to have more positive and less negative emotions than they actually experienced. For our current purpose, only the findings on ideal affect are discussed.

However, cultural differences were found in the type of ideal affect, such that European Americans and Chinese Americans valued high-activation positive emotions more than did the Chinese. Conversely, Chinese and Chinese Americans valued low-activation positive emotions more than did European Americans. Tsai et al. (2006) propose a link between ideal affect and the preferred type of environmental control. Westerners prefer *influence*, and Easterners prefer adjustment. According to the authors,

to successfully influence or change the physical or social environment, a person must be able to *mobilize* resources. Because high activation states facilitate mobilization of resources, people with influence goals should value *high activation positive states*; in contrast, low activation states promote attention to environmental stimuli, people with *adjustment* goals should value low activation states. (p. 290; emphasis added)

Emotion Norms

Positive emotions are not necessarily evaluated as positive, nor are negative emotions necessarily negative. Eid and Diener (2001) compared the emotion norms in four countries: two with independent (United States, Australia) and two with interdependent (China, Taiwan) cultural models. They expected that people in cultures with an independent model would tend to focus on positive information about the self; thus, they would value self-conscious emotions such as pride, signaling that personal goals have been accomplished, but would negatively evaluate emotions such as guilt, signaling negative self-information.

Interdependent models, on the other hand, were expected to further a focus on negative information about the self, because this informa-

tion is important to prevent one from violating social norms; thus, these people were expected to value guilt positively. In these interdependent contexts, pride would make an individual stand out, thus being seen as inappropriate and undesirable. Interdependent models were predicted to lend positive meaning to this negative emotion, and negative meaning to the positive, self-conscious emotion.

In fact, in this study (Eid & Diener, 2001), pride was largely desirable and guilt largely undesirable, in countries with independent models.⁴ Furthermore, the majority of people living in independent cultural contexts valued all positive emotions (joy, affection, pride, contentment) positively and all negative emotions (anger, fear, sadness, guilt) negatively. The emotion norms in the interdependent contexts were both different and more numerous. For example, two patterns of positive emotion norms were found about equally often in China. By both Chinese patterns of norms, pride and contentment were assessed as somewhat negative. Taiwanese tended to evaluate joy, affection, and contentment as positive, but pride as neutral or negative. Thus, as expected by the authors, people in interdependent contexts tended to consider some positive emotions as undesirable or inappropriate.

The opposite was found for the negative emotion norms as well. The emotion norms among Australians and Americans, as well as among some Taiwanese, assessed all negative emotions (anger, fear, sadness, and guilt) as undesirable or inappropriate.⁵ A good percentage of Chinese, and a somewhat smaller part of Taiwanese, however, evaluated guilt as a positive or neutral emotion; guilt was definitely deemed more undesirable in independent contexts.

Overall, the norm patterns for negative emotions were less clear, and all cultures had more heterogeneous norms for negative emotions than for positive. As Eid and Diener (2001) acknowledge, a better picture of the emotion norms in a culture may be obtained when examining specific situational norms.

Emotion Norms and Ideals Shape Emotional Experience

Ideal and normative affect are more than statements of preference. Tsai and her colleagues (2006) powerfully demonstrated that culturally ideal emotions are important predictors of de-

pression (as measured by the Center for Epidemiologic Studies—Depression Scale [CES-D]). Depression in the European American group was accounted for by the discrepancy between actual and ideal high-activation positive emotion (HAP), and only marginally by low-activation positive emotion (LAP). In the Chinese group, on the other hand, depression was accounted for by the discrepancy between actual and ideal LAP, and not by HAP. This is consistent with the Chinese focus on adjustment.

Interestingly, the only group for which the discrepancies between actual and ideal affect for both HAP and LAP predicted depression was the Chinese American group, which also reported high levels of both HAP and LAP as ideal emotions. Therefore, the ideal emotions in a culture are not only statements about emotions, but, importantly, they also constitute the emotional experience.

That emotion norms shape emotional experience was also suggested in the study by Eid and Diener (2001), discussed earlier. For each of the four countries (China, Taiwan, United States, and Australia), low- to medium-sized correlations were found between positive emotion norms and emotional experience for both the frequency and the intensity of emotional experience. Thus, the cultural norms and ideals for positive emotion shape the patterns of emotional experience. The correlations between negative emotion norms and emotional experience were less strong.

Regulation Goals

Cultural models appear to influence the goals of emotional regulation. Whereas American independent models appear to promote happiness and deemphasize unhappiness, the importance of experiencing both good and bad feelings, and moderating both, is stressed in East Asian contexts (Lu, 2001; Minami, 1971; Ng, Ho, & Smith, 2003). Striving for emotional balance is normative in the latter contexts (Heine et al., 1999), because it signals maturity and role fulfillment.

The evidence for cultural differences in regulatory goals is only indirect. Cultural differences in regulation are inferred from the following findings: (1) Over time, Americans report more positive than negative emotions, and East Asians report a balance between the two; and (2) in experimental tasks, Americans

seek out events that are likely to elicit positive affect, whereas East Asians prioritize tasks that prepare them to meet social standards over tasks that are likely to produce positive affect.

Prevalence of Positive Affect or Emotional Balance?

The relative prevalence of positive emotions in North American as compared to Asian cultures has been established both in online measurements of emotion (Mesquita & Karasawa, 2002; Scollon, Diener, Oishi, & Biswas-Diener, 2004; Tsai & Levenson, 1997) and in retrospective reports (Oishi, 2002). For example, in a large experience-sampling study, Mesquita and colleagues sampled the emotions of American, Japanese, and Taiwanese students for 1 week (Mesquita & Karasawa, 2002; Mesquita, Karasawa, & Chu, 2007). Four times a day, students were asked to recall the last emotion they had experienced during the preceding 3-hour interval. Using a bidimensional scale of pleasantness–unpleasantness, Mesquita and colleagues found that American students, on average, appraised the emotional situations in their lives as better than neutral, whereas Japanese and Taiwanese students evaluated their lives on average as neither positive nor negative.

Other studies with different methodologies have established convergent results. Dating European American couples, who watched a tape of their just-completed discussion, reported more positive than negative emotions, whereas Asian American couples reported similar ratios of positive and negative affect (Tsai & Levenson, 1997). Respondents provided the continuous reports of their emotions while watching the videotaped interaction. The experience-sampling studies, as well as the online couple study, were designed to reduce retrospective bias by having respondents report emotions very close to their actual experience. Thus, the emphasis on positive emotions appears to be present in online experiences.

In addition to having more positive experiences, European Americans tend to remember events more positively than do Asians, even if the two groups initially appraised situations as equally positive. In several experiments, European Americans retrospectively rated their satisfaction with a task significantly higher than did Asian Americans, despite the lack of cultural differences in the ratings at the time of that task (Oishi, 2002). Thus, European Amer-

icans tend to remember and represent their emotional lives as more positive than did Asian Americans, in part because they remember their feelings as more positive than they actually were at the moment.

The positive memory bias does not always replicate for European Americans. In one experience-sampling study, Scollon and her colleagues (2004) found that all five cultural groups in the study, European Americans included, underestimated the frequency of their positive emotions in retrospective reports compared to online reports of the same emotions.

The same experience-sampling study provided evidence for balanced emotional styles in East Asian cultures (Scollon, Diener, Oishi, & Biswas-Diener, 2005). Respondents in this study rated their emotions seven times a day for 1 week. The number of positive emotions East Asians (Japanese, Indians, and Asian Americans) reported was positively associated with the number of negative emotions reported. In the two other cultural contexts (European Americans, Hispanics in the United States), there was no significant relationship between positive and negative emotions. The results suggest that, over time, positive emotions in East Asian contexts seem to be moderated or balanced out by negative emotions, whereas this is not the case in the U.S. contexts.

The experience-sampling study also clarifies that East Asian groups did not experience positive and negative emotions at the same moment. This suggests that previous findings that people who experience more positive emotions in those cultures also experience more negative emotions (Bagozzi, Wong, & Youjae, 1999; Kitayama et al., 2000) can best be interpreted as reports over time. Similarly, studies that suggest no relationship between experiencing positive and negative emotions in East Asian context (Schimmack, Oishi, & Diener, 2002) may best be interpreted as reports over time. The two styles of regulation associated with East Asian contexts contrast with the North American experience of positive emotions at the cost of negative emotions.

There is some evidence that the cultural differences in regulatory style are driven by positive rather than negative events. Leu and her colleagues (2007) provided Chinese, Japanese, and American respondents with standardized events in the form of a diary. The diary episodes included both positive and negative events. In the North American group, there

was clear evidence for the emphasis on positive emotions at the expense of negative emotions in response to the positive events. Whereas Japanese and Chinese moderated their positive emotions with negative emotions (e.g., citing both happiness and fear of being too happy), European Americans reported positive emotions, almost to the exclusion of negative emotions. In the negative situations, however, no cultural differences in the relationship between positive and negative emotions were found. Thus, when something bad happens, individuals in all three cultures try to see the positive side of it, and to feel some positive affect as well; however, when something good happens, only the Chinese and Japanese try to see the negative side of it. This appears to represent the larger emphasis on maximizing positive feelings and minimizing negative feelings among European Americans, in contrast to a focus on moderating positive and negative emotions among East Asians.

Good Feelings Are Not a Universal Motive

Very important in much of the foregoing discussion is that maximizing positive affect to the exclusion of negative affect is not a universal motive. A number of recent experimental studies comparing task motivation between European American and either Japanese or Asian American respondents (Heine et al., 2001; Oishi & Diener, 2001, 2003) suggest this too. In these studies, North Americans sought out events that they liked, but Japanese (Asian Americans) did not. In one experiment (Heine et al., 2001), respondents received either failure or success feedback on a particular task (e.g., a word association test). All respondents were then given the opportunity to spend more time on the task. Though Japanese and European American respondents both *liked* the success feedback better than the failure feedback, Japanese respondents were motivated to work on a task after failure feedback, whereas European Americans were motivated by success feedback. Apparently, a task that proves pleasurable is not universally motivating.

In another study, Asians and European Americans solved anagrams and rated their enjoyment of the task and its difficulty right after finishing (Oishi & Diener, 2003). About 1 month later, participants were asked either to perform the same task again, or to do a comparable, new task. The more European Ameri-

cans enjoyed the task the first time, the more likely they were to select it a month later; for the Asian participants, there was no relation between enjoyment and task selection. Thus, positive affect was not a motive for Asian participants.

Based on these studies, we postulate that pursuing positive affect is normative when feeling good about oneself is the goal, as appears to be the case in European American cultural contexts. However, when meeting social standards is the goal, self-improvement takes precedence over feeling good. The latter seems to happen in Japanese and Asian American contexts.

In Conclusion

Cultures, as well as individuals within those cultures, have different representations of the emotions that are desirable or normative. The study of ideal and normative representations brings out an important way in which emotional lives can be different across cultures and, moreover, illustrates that differences in emotion ideals and norms importantly and differentially inform emotional experience and behavior. At the same time, the work on normative and ideal emotions is underdeveloped. The concepts are both insufficiently demarcated and related to each other (but see Tsai et al., 2006). It is not clear, for example, whether people are capable of reporting norms regarding the focal emotions in their culture, or to what extent a person's ideal emotions are derived from culturally endorsed emotion norms. Finally, the mechanisms by which focal, normative, and ideal emotions shape the emotional experience are virtually unexplored.

Beyond Independent and Interdependent Models

The majority of the research reviewed here contrasts the emotions in North American and East Asian contexts. These studies have contributed greatly to an understanding of how culture influences emotion. However, there is a need to move beyond characterizations of cultures as either independent or interdependent, and to address emotions in other cultural contexts. The little evidence collected on emotions in other cultural contexts suggests that we have to consider cultural models of self and relating in more detail than is currently the case.

A study by Schimmack et al. (2002) makes this point. In this study, the zero correlation between positive and negative emotions was shown to be exclusive to East Asian cultures rather than characteristic of collectivist cultures generally. When Schimmack et al. controlled for the East Asian philosophical tradition of a country, collectivism did not contribute any variance to this emotional pattern. Thus, the study shows that our understanding of emotional experience in different cultures is furthered by an understanding of different kinds of interdependent models.

Other studies also demonstrate that the distinction between independent and interdependent cultural models does not suffice for a comprehensive understanding of cultural differences in emotional experience. For instance, there is now ample evidence to suggest that some non-Asian groups from interdependent cultural contexts have high positive affect, higher even than that of European Americans. Thus, in an experience-sampling study, Scollon et al. (2004) found that Hispanic students in California scored significantly higher than European American university students on positive emotions, followed by Asian students both in the United States and in Asia. The elevated positive ratings for Hispanics were found with respect to online ratings, global ratings, and retrospective ratings of positive affect. Furthermore, Hispanics and European American respondents reported somewhat lower negative emotion than did the Asian groups. Hispanics and Asians, both engaging in interdependent models, could not have been more different with respect to their emotions.

Albert and Mesquita (2005) had similar results with low-acculturation and low-education Mexicans in North Carolina. Compared to European Americans who were matched in education, Mexican immigrants reported feeling more positive and less negative emotions on an emotion scale (Barrett & Russell, 1998).

Not much is known about Mexican interdependent models, but it is clear that this kind of interdependence has radically different implications for emotional experience. Whereas East Asians (Japanese in particular) have been described as moderating their positive feelings to fit in with others and fulfill their roles, Mexican contexts do not prescribe this type of emotion regulation. Rather, happiness in Mexican contexts is intertwined with interdependence

and seems to be culturally encouraged. Emotional expressivity is valued (Klein, 2001). Happiness and happy events are seen as assets rather than obstacles for role fulfillment and social adjustment. Happiness is explicitly associated with interdependence in relationships.

At the same time, negative events appear to be downplayed in Mexican cultural contexts, which emphasize that one's individual problems are less important than fulfilling one's roles in social life (Valdes, 1996). Difficulties should be accepted (Diaz-Gerrero, 1967). Acceptance and resignation, rather than self-criticism, appear to be required for role fulfillment. One is supposed to deal with the difficulties the best that one can, without dwelling on them (Valdes, 1996). Though this is far from a comprehensive description of Mexican cultural models, the outlines make it clear that interdependence, and therefore the emotions in different interdependent contexts, can take very different forms.

DISCUSSION

A Cultural Perspective on Emotions

Examining culturally particularized emotions yields some important insights into the nature of emotion generally. These insights would not have been obtained without careful examination of the way emotions fit with the cultural models in which they occur.

Emotions as Social, Relational Phenomena

First, emotions are social phenomena. They are about the relationships between people rather than being strictly personal phenomena within the heart or the head of an individual. Even in cultures that stress the relative independence of different individuals in relationships, as is the case in North American culture (Rothbaum, Pott, Azuma, Miyake, & Weisz, 2000), emotions tend to contribute to the normative type of relationship. Emotions in North American contexts tend to underline the autonomy of people in relationships (Mesquita et al., 2005; Rothbaum, Weisz, Pott, Miyake, & Morelli, 2000), which is the condoned relationship format in this context. On the other hand, emotions in interdependent contexts underline and realize the interdependent relationships in these cultures (Kitayama et al., 2006).

Emotions Are Rooted in Collective Meanings

Second, emotions are not merely subjective individual phenomena. Rather, emotions constitute the cultural models. They are constructions of the emotional situation, based on cultural meanings and practices, and they are goals that make sense only within the parameters of the cultural models.

Collective Representations of Emotions Influence Experience

Third, emotions are not just online experiences that happen to occur. Cultural representations of emotions, especially focal emotions, emotion norms, and ideal affect, motivate the experience of emotions. They do so by facilitating positively valued emotional experiences and inhibiting negative emotional experiences. Emotion representations also are the standards by which the significance of emotions is judged (see Tsai et al., 2006).

The cultural psychology of emotions is not the enterprise of endlessly mapping all possible variations in experience. Rather, a cultural-psychological approach allows for the inference of general principles of emotion through careful descriptive study of the emotional phenomena as they actually occur in their culturally particular forms. The end goal of cultural psychology, like the end goal of all science, is the reduction of rich data to general principles. However, *only* an abstraction that acknowledges the central place of meaning in emotional experience and behavior can really contribute to our understanding of people's actual emotional experience and behavior.

Methods

If culture matters so much, why do so many studies find cross-cultural convergence in emotional phenomena? There are probably two reasons. One has to do with research design and the other, with interpretation of the results.

Research Design

Cross-cultural convergence in emotional phenomena can often be attributed to the use of methods that do not reveal important cultural differences. In a way, one has to be aware of what the differences might be to create paradigms that allow for establishing them. One

has to have a theory of emotional differences to measure them. For example, it would have been impossible to discover that Japanese respondents identify the emotion in a person's face by considering not only that person's facial expression but also the expressions of others in the same environment, had they not been presented a picture displaying several people at once. The traditional paradigm of showing one isolated face without any social context would not have yielded cultural differences in this respect. Similarly, many experimental designs have placed individuals in a situation by themselves (for an exception, see Tsai & Levenson, 1997). It is very unlikely that conditions in which an individual is isolated from his or her social environment will reveal any of the emotional differences associated with differences in the normative relationships between people.

Likewise, many studies are confined to emotions that are salient in Western cultures, and compare these emotions with the translated counterparts in other cultures. It is often not at all clear that these emotions are equally relevant in the cultures of comparison. Certainly, including emotions on the basis of their relevance for another, non-Western culture has been shown to change the results of emotion research. Thus, for example, Kitayama and his colleagues added typical Japanese emotion words to words that are salient in Western cultures, and found a dimension of social engagement that accounted for substantial variance in emotional experience (Kitayama et al., 2000; Kitayama et al., 2006). This dimension could not have been found in cross-cultural research that included only the translations of commonly used English emotion words (Russell, 1983). Importantly, establishing cultural differences in emotions seems to require a theory about the kinds of differences that one might find, as well as the methods that are capable of revealing these differences.⁶

Interpretation of Data

Practices in data interpretation have also contributed to the common conclusion of emotional similarity. As discussed, many studies have described the phenomena at so abstract a level that it would be hard to imagine *not* finding cross-cultural similarities. For example, Scherer and Wallbott (1994) looked at the antecedent events of emotions and found substantial consistency in the antecedent events associ-

ated with particular classes of emotions. However, the categories used to code the events were rather abstract. For example, “relationships” constituted one category that was universally the most important elicitor of joy-emotions. This finding seems to be descriptive of a condition of human life—and is interesting in that way—but it does not help to specify the emotional experience in particular cultures. It is questionable, for example, that knowing a positive emotion is elicited by “relationships” will help one to understand or predict the precise appraisals, behavioral goals, and behaviors that are likely to follow.

Another practice in cross-cultural research on emotions is to conclude universality when the percentage of a certain response is higher than chance. However, depending on the number of answers possible, the chance rate of responses can be as low as 18% (for six response options). Although it is important that people associate certain behaviors (Consedine, Strongman, & Magai, 2003), facial expressions (Matsumoto, 1996), and antecedent events (Boucher & Brandt, 1981) significantly more often with the same emotions than would occur by chance, the research does not show that behaviors, facial expressions, and antecedent events are universal. It shows that there is some universal human aspect in these different facets in emotions. The actual emotions may still reveal a lot of cultural specificity.

Differences in Emotion Talk or Emotional Experience?

Much, though certainly not all, of the research that we have reported consists of verbal reports from people in different cultures. Some might comment that whereas the ways people “talk” about their emotions may differ across cultures, the emotions themselves do not (e.g., Ekman, 1992). We maintain that emotional experience itself is different across cultures, and, importantly, that meanings are driving these differences.

There is growing evidence that cultural differences in emotion go beyond the emotion discourse, and that emotional meanings are consequential and affect the kinds of behavior reported. Many behaviors can be explained from the emotional meanings as construed, and this is true for behaviors reported for protagonists in emotional vignettes (e.g., Bagozzi et al., 2003), for self-reported behaviors in past emo-

tional episodes (e.g., Mesquita et al., 2005), and for behaviors such as those observed in ethnographies (e.g., Briggs, 1970).

Cultural construals of emotional situations are also consistent with the results yielded by experimental judgment tasks related to facial expressions. Thus, differences in emotion identification are consistent with the differences between independent and interdependent construals of the situation (Cohen & Gunz, 2002; Masuda et al., 2005). In independent contexts, judgments of facial expressions are based on the emotions of one individual only, whereas judgment of emotions in interdependent cultures is based on the perception that people’s emotions are interdependent.

Furthermore, there is clear evidence that the meaning of emotions themselves is consequential. Emotion norms and ideals have been associated with choice behaviors (Oishi & Diener, 2003). Thus, feeling good is an important motive in cultures that value positive emotion, whereas it does not motivate people in cultural contexts that emphasize emotion moderation and role fulfillment. Similarly, cultural evaluations of emotional states are important predictors of depression (Tsai et al., 2006), and of emotional experiences in general (Eid & Diener, 2001). Thus, cultural meanings of emotions themselves are important predictors of both behavior and affective experience.

In summary, understanding the variance in cultural meanings of emotions is an important condition for the understanding of emotional experience itself.

NOTES

1. A functional view does not mean that every instance of emotion fits the cultural goals and practices. It means that, on average, the cultural shaping of emotions renders them more effective in a cultural context than if they were not shaped to fit the cultural model.

2. The Indian students were an exception compared to individuals in the other interdependent cultures.

3. One possible explanation for the difference in types of shame responses is that words representing shame in different cultures simply divide the domain of emotional experience differently. In that case, studies comparing these emotional experiences across cultures by requesting for an experience using the word *shame* would simply prompt different parts of the emotion domain. In support of this hypothesis, Japanese has a single word denoting both shame and embarrassment (Rusch, 2004), and Chinese reportedly has five words for shame alone (Frank, Harvey, & Verdun, 2000). It is

unclear, however, that these differences in vocabulary are solely responsible for the different experiences. First, it is entirely possible that the Japanese do not distinguish sharply between the different uses of the shame word, and that different experiences of this word are experienced as sharing lots of similarities. This would be consistent with findings reported by the anthropologist Daniel Fessler, who studied shame experiences among the inhabitants of a fisher village in the Indonesian province of Bengkulu. Whereas Malay, the language these villagers speak, has only one word that refers to both shame and embarrassment, Fessler concludes that *malu* does not encompass different homonyms. Bengkulu villagers in the Indonesian described the feelings and action tendencies of *malu* as no different when the emotion occurs in classical shame situations compared to embarrassment situations (Fessler, 2004). Second, despite having one rather than five shame words, Americans were perfectly able to distinguish between the five different forms of shame that the Chinese language distinguishes (Frank et al., 2000). Thus, it is not obvious that the differences in shame behaviors are associated with differences in word use.

4. The description of these data is simplified for the purposes of this chapter. In fact, the authors calculate latent classes of people. Some of these latent classes are culturally specific, but most were found across cultures. If a respondent's data fit into a class, this reflects the *likelihood* that this respondent values certain emotions as desirable, undesirable, or neutral. We simplified the data by describing the latent classes to which most respondents in a culture belong and, within each class, the emotion norms that are most likely to be observed.

5. Some Australians and Americans, however, considered anger and sadness as positive emotions.

6. This is, of course, not to deny the cross-cultural similarities in emotions that are found when one studies English emotion terms. There is certainly reason to assume some shared core of emotional experiences based on the research (Oishi et al., 2004; Scherer, 1997; Scherer & Wallbott, 1994; Scollon et al., 2004). The relative importance of these similarities compared to the differences cannot be judged based on the available evidence.

CHAPTER 31

Passionate Love and Sexual Desire

ELAINE HATFIELD
RICHARD L. RAPSON
LISE D. MARTEL

Passionate love is a universal emotion experienced by almost all people, in all historical eras, and in all the world's cultures (see Fischer, Shaver, & Carnochan, 1990; Shaver, Morgan, & Wu, 1996). Yet despite its universality, culture has been found to have a profound impact on people's definitions of love and on the way they think, feel, and behave in romantic settings. Cross-cultural studies provide a glimpse into the complex world of emotion and allow us to gain an understanding of the extent to which people's emotional lives are written in their cultural and personal histories, as well as "writ in their genes" and evolutionary history, and in the interaction of the two (Tooby & Cosmides, 1992).

PASSIONATE AND COMPANIONATE LOVE

Defining Love

Poets, novelists, and social commentators have proposed numerous definitions of love. Ahdaf Soueif (1999), an Arab novelist, once poetically described the multitude of meanings that "love" possesses in Arabic:

"Hubb" is love, "ishq" is love that entwines two people together, "shaghaf" is love that nests in the chambers of the heart, "hayam" is love that wanders the earth, "teeh" is love in which you lose yourself, "walah" is love that carries sorrow within it, "sababah" is love that exudes from your pores, "hawa" is love that shares its name with "air" and with "falling," "gharm" is love that is willing to pay the price. (pp. 386–387)

Cultural theorists have long been interested in the impact of culture on the meaning that young men and women ascribe to "love." Scholars usually distinguish between two kinds of love: "passionate love" and "companionate love" (Hatfield & Rapson, 1993).

Passionate Love

Passionate love (sometimes called "obsessive love," "infatuation," "lovesickness," or "being in love") is a powerful emotional state. It has been defined as

a state of intense longing for union with another. Passionate love is a complex functional whole including appraisals or appreciations, subjective

feelings, expressions, patterned physiological processes, action tendencies, and instrumental behaviors. Reciprocated love (union with the other) is associated with fulfillment and ecstasy. Unrequited love (separation) is associated with feelings of emptiness, anxiety, and despair. (Hatfield & Rapson, 1993, p. 5)

People in all cultures recognize the power of passionate love. In South Indian Tamil families, for example, a person who falls head-over-heels in love with another is said to be suffering from *mayakkam*—dizziness, confusion, intoxication, and delusion. The wild hopes and despairs of love are thought to “mix you up” (Trawick, 1990).

The Passionate Love Scale (PLS) was designed to tap into the cognitive, emotional, and behavioral indicants of such longings (Hatfield & Sprecher, 1986). The PLS has been found to be a useful measure of passionate love with men and women of all ages, in a variety of cultures, and has been found to correlate well with certain well-defined patterns of neural activation (see Bartels & Zeki, 2000, 2004; Doherty, Hatfield, Thompson, & Choo, 1994; Fisher, 2003; Landis & O’Shea, 2000).

Companionate Love

Companionate love is a far less intense emotion. It combines feelings of attachment, commitment, and intimacy (Hatfield & Rapson, 1993). It has been defined as “the affection and tenderness we feel for those with whom our lives are deeply entwined” (p. 9).

Psychologists have used a variety of scales to measure companionate love. Since Sternberg (1988) postulated that companionate relationships require both commitment and intimacy, many researchers have assessed such love by measuring those two components.

Other Definitions of Love

Scientists have proposed a variety of definitions and typologies of love (see Hendrick & Hendrick, 1989; Shaver & Hazan, 1988; Sternberg, 1988). According to Sternberg, for example, types of love are determined by various combinations of passion, intimacy, and commitment. Possible combinations result in romantic love, infatuation, companionate love, liking, fatuous love, empty love, and consummate love.

In this chapter we focus on passionate love; we touch upon other varieties of love only briefly, if at all.

THEORETICAL UNDERSTANDINGS OF PASSIONATE LOVE

Anthropological Perspectives on Passionate Love

Passionate love is as old as humankind. The Sumerian love fable of Inanna and Dumuzi, for example, was spun by tribal storytellers in 2,000 B.C.E (Wolkstein, 1991). Today, most anthropologists argue that passionate love is a universal experience, transcending culture and time (Buss, 1994; Hatfield & Rapson, 1996; Jankowiak, 1995; Tooby & Cosmides, 1992).

Jankowiak and Fischer (1992) drew a sharp distinction between “romantic passion” and “simple lust.” They proposed that both passion and lust are universal feelings. Drawing on a sampling of tribal societies from the Standard Cross-Cultural Sample, they found that in almost all of these far-flung societies, young lovers talked about passionate love, recounted tales of love, sang love songs, and spoke of the longings and anguish of infatuation. When passionate affections clashed with parents’ or elders’ wishes, young couples often eloped.

Social anthropologists have explored folk conceptions of love in such diverse cultures as the People’s Republic of China, Indonesia, Turkey, Nigeria, Trinidad, Morocco, the Fulbe of North Cameroun, the Mangrove (an aboriginal Australian community), the Mangaia in the Cook Islands, Palau in Micronesia, and the Taita of Kenya (see Jankowiak, 1995, for a review of this research). In all these studies, people’s conceptions of passionate love appear to be surprisingly similar.

Anthropologists have also been interested in the kinds of societies in which our primate ancestors lived. Sommer (1993), for example, asked a challenging question: Did our ancient *Homo sapiens* ancestors live in monogamous, polygamous, polyandrous, or polygynandrous communities? (In monogamy, a man and woman marry—usually for a lifetime. In polygamy, one man may possess many wives; in polyandry, one woman may take several husbands. In polygynandry, or “promiscuous” mating, men and women may mate at will.)

After observing many kinds of primates, Sommer (1993) discovered that it is easy to predict what sort of sexual mating arrange-

ments a primate species will adopt. He needed to know only four facts:

1. In that species, who is bigger—the males or the females?
2. How much do the males' testes weigh?
3. Do females have sexual swellings (which signal sexual receptivity and fertility)?
4. How long does sexual intercourse last?

(The scientists found, for example, that in monogamous species such as gibbons, males and females are generally about the same size. In polygynous species such as orangutans [where successful males must physically dominate their rivals], males are much larger than their mates.)

When Sommer (1993) classified *H. sapiens* on these four characteristics, his calculations led him to conclude that although our human forebears *may* have been monogamous, the odds are that they were polygynous.¹ There is no chance that they were either polyandrous or polygynandrous.

What about our more immediate ancestors? How did they live? On the basis of her calculations, Fisher (1989) concluded that throughout the world, although (in theory) most societies are polygynous, in fact, the overwhelming majority of married men and women are actually in monogamous marriages. Fisher studied the marital arrangements of the 853 societies sampled in the *Ethnographic Atlas* (which contains anthropological information on more than 1,000 representative preindustrial societies throughout the world). She found that although almost all societies (84%) permitted polygyny, men rarely exercised this option. (Only about 10% of men possessed more than one wife. Most possessed just one wife. A few were unmarried.) In 16% of societies, monogamy was prescribed. Polyandry was extremely rare. Only 0.5% of societies permitted polyandry. In recent years, however, theorists such as Wilson and Daly (1992) have observed that in humankind's long evolutionary history, although men and women in theory are "supposed" to be faithful to one partner, in many situations it was of benefit to break the rules and "mate poach." Thus, humans are likely to possess a variety of cognitive structures designed to deal with a multitude of contingencies (for a discussion of the factors that made and make it advantageous (or costly) for men and women to seek a variety of sexual partners,

see Barkow, Cosmides, & Tooby, 1992; Hrdy, 1999; Wilson & Daly, 1992).

Genetic and Biological Perspectives on Love

Recently, social psychologists, neuroscientists, and physiologists have begun to explore the links between love, sexual desire, and sexual behavior.

The first neuroscientists to study passionate love were Birbaumer, Lutzenberger, Elbert, Flor, and Rockstroh (1993). They concluded (on the basis of their EEG [electroencephalogram] assessments) that passionate love is "mental chaos." More recently, Bartels and Zeki (2000, 2004) studied the neural bases of passionate love using fMRI (functional magnetic resonance imaging) techniques. They interviewed young men and women from 11 countries and several ethnic groups who claimed to be "truly, deeply, and madly" in love, and who scored high on the PLS. The authors concluded that passionate love leads to a suppression of activity in the areas of the brain controlling critical thought; they argued that once we get close to someone, there is less need to assess their character and personality in a negative way. Passion also produced increased activity in the brain areas associated with euphoria and reward, and decreased levels of activity in the areas associated with distress and depression. Activity seemed to be restricted to foci in the medial insula and the anterior cingulate cortex and, subcortically, in the caudate nucleus, and the putamen, all bilaterally. Deactivations were observed in the posterior cingulate gyrus and in the amygdala, and were right-lateralized in the prefrontal, parietal, and middle temporal cortices.

What is the conclusion?

We conclude that human attachment employs a push-pull mechanism that overcomes social distance by deactivating networks used for critical social assessment and negative emotions, while it bonds individuals through the involvement of the reward circuitry, explaining the power of love to motivate and exhilarate. (Bartels & Zeki, 2004, p. 1155)

The authors also found passionate love and sexual arousal to be tightly linked.

Other psychologists who have studied the links between passionate love and sexual desire (using fMRI techniques) have found similar results. Fisher (2003, 2004), for example, investi-

gated the brain chemistry of men and women passionately in love (again using the PLS scale) and found that passionate love markedly increases sexual motivation.

In parallel with this research, a number of social psychologists, neurobiologists, and physiologists have explored the neural and chemical substrates of passionate love, sexual desire, and sexual mating (Carter, 1998; Komisaruk & Whipple, 1998; Marazziti, Akiskal, Rossi, & Cassano, 1999; Marazziti & Canale, 2004).

Scientists interested in the chemistry of passionate love have found that a variety of neurochemicals shape passionate love and sexual desire. According to Fisher (2004), for example, romantic love is associated with the natural stimulant dopamine and perhaps norepinephrine and serotonin. Lust is associated primarily with the hormone testosterone in both men and women. (Estrogen may decrease desire.) Attachment is produced primarily by the hormones oxytocin and vasopressin (see also Hyde, 2005; Marazziti & Canale, 2004; Regan & Berscheid, 1999).

Psychologists' opinions may differ on whether romantic and passionate love are emotions (Aron et al., 2005; Shaver et al., 1996) and whether passionate love, sexual desire, and sexual motivation are closely related constructs (both neurobiologically or physiologically) or very different in nature (Aron et al., 2005; Diamond, 2004; Hatfield & Rapson, 1987). Nonetheless, this pathbreaking research has the potential to answer age-old questions as to the nature of culture, love, and human sexuality.

In spite of the fact that anthropologists, neurobiologists, and physiologists consider passionate love to be a panhuman characteristic (an emotion thought to exist in all cultures and in all historical eras), culture has been found to exert a profound impact on people's romantic and sexual attitudes, emotions, and behaviors.

Historical Perspectives on Love

Any time scholars begin talking glibly about "cultural universals," historians tend to react with skepticism. Historians prefer to emphasize the multiplicity, variability, and mutability of human behavior. They shy away from all single-cause explanations for how cultures and individuals work, and they revel in complexity, movement, and change.

Not surprising, then, when it comes to romance, historians invariably note that passionate attitudes and behaviors have varied dramatically from one culture to another or from one temporal period to the next. Some typical examples include the sage Vatsayana advising men and women to marry for love or the Medieval church condemning such sinful indulgence; early Egyptians practiced birth control, and some Polynesians practiced infanticide; Classical Greeks rewarded couples who were willing to conceive; Eskimos considered it hospitable to share their wives with visitors; Muslims jealousy locked their wives and concubines away in harems; Sumerian and Babylonian temples were staffed by priests, priestesses, and sacred prostitutes; the ancient Hebrews stoned "godless" prostitutes; Hellenes idealized the pure sexual love between older men and young boys; and the Aztecs punished homosexuality by tying men to logs, disemboweling them, covering them with ash, and incinerating them (Tannahill, 1980).

Historians have also documented how profoundly a society's attitudes toward love, sex, and intimacy can alter over time. Consider China, which possesses an ancient culture. Its archeological record begins 5,000 years ago in the *Hongshan* (Red Mountain) dynasty. Its historical record begins 4,000 years ago in the *Xia* (or First Dynasty). The oldest Chinese medical texts on love and sexuality date from 168 B.C.E.

Traditionally, Chinese history is divided into three periods: the Formative Age (prehistory through 206 B.C.E.), the Early Empire (206 B.C.E. to 960 C.E.), and the Later Empire (960–1911 C.E.). The Chinese historian Ruan (1991) argued that during the first 4,000 years of Chinese history, attitudes toward passionate love and sexual desire were generally positive—although hardly uniform and unchanging during these epochs. Medical texts dating back to 168 B.C.E. make it clear that the ancients assumed that love and sexual pleasure were two of the great joys of life. In the Late Empire (1,000 years ago), during the Sung Dynasty, the Neo-Confucianists gained political and religious power, and Chinese attitudes began to alter, gradually becoming more and more negative and repressive concerning sex. Displays of love outside marriage were forbidden, and erotic art and literature were often burned.

When the People's Republic of China was established in 1949, Communist officials imposed even tighter controls on love and "inap-

appropriate” sexual activity. On a visit to Beijing, Money (1977) reported: “I came across a slogan: ‘Making love is a mental disease that wastes time and energy’ ” (p. 543).

Gil (1992) noted:

A puritanical, if not heavy-handed, sexual “primness” became firmly established. . . . This included a denial of romantic love, the affirmation of the absolute role of the collective over the individual as a basic tenet toward which one should direct any affections. The Great Leap Forward demanded, in Communist parlance, the “renunciation of the heart.” Party policy deliberately constructed an altruism which sought (for every man and woman) hard work during the day, without being “deflected or confused” by love, sexual desire, or any strivings for private happiness. (p. 571)

Today, of course, in China as throughout much of the rest of the world, the winds of change are wafting. Young people—perhaps as a consequence of globalization (as evidenced in the availability of international cinema, the Web, world travel, and MTV)—are adopting more “liberal” or “worldly” views of passionate love, sexual desire, marriage for love (rather than arranged marriages), and romantic and sexual diversity. In China, then, things appear to have come full circle.

Historical research, then, reminds us that throughout time, people have embraced very different attitudes toward romantic and passionate love, have ascribed very different meanings to “love,” have desired very different traits in romantic partners, and have differed markedly in whether such feelings were to be proclaimed to the world or hidden in the deepest recesses of the heart. In the real world, human sexual attitudes and behavior seem forever in flux.

Culture and Passionate Love

Americans are preoccupied with love—or so cross-cultural observers once claimed. In a famous quip, Linton (1936) once mocked Americans for their naive idealization of romantic love and their assumption that romantic love was a prerequisite to marriage:

All societies recognize that there are occasional violent, emotional attachments between persons of opposite sex, but our present American culture is practically the only one which has attempted to

capitalize these, and make them the basis for marriage. . . . The hero of the modern American movie is always a romantic lover, just as the hero of the old Arab epic is always an epileptic. A cynic may suspect that in any ordinary population the percentage of individuals with a capacity for romantic love of the Hollywood type was about as large as that of persons able to throw genuine epileptic fits. (p. 175)

Throughout the world, a spate of commentators have echoed Linton’s claim that the idealization of passionate love is a peculiarly Western institution.

A Bit of Background

The world’s cultures differ profoundly in the extent to which they emphasize individualism or collectivism (although some cross-cultural researchers focus on related concepts: independence or interdependence, modernism or traditionalism, urbanism or ruralism, affluence or poverty).

Individualistic cultures such as the United States, Britain, Australia, Canada, and the countries of Northern and Western Europe tend to focus on personal goals. Collectivist cultures such as China, many African and Latin American nations, Greece, southern Italy, and the Pacific Islands, on the other hand, press their members to subordinate personal interests to those of the group (Markus & Kitayama, 1991; Triandis, McCusker, & Hui, 1990). Triandis and his colleagues point out that in individualistic cultures, young people are allowed to “do their own thing”; in collectivist cultures, the group comes first.

Hsu (1953, 1985) and Doi (1963, 1973) contend that passionate love is a Western phenomenon, almost unknown in China and Japan—and so incompatible with Asian values and customs that it is unlikely ever to gain a foothold among young Asians. Hsu (1953) writes: “An American asks, ‘How does my heart feel?’ A Chinese asks, ‘What will other people say?’ ” (p. 50). Hsu points out that the Chinese generally use the term “love” to describe not a respectable, socially sanctioned relationship, but an *illicit* liaison between a man and a woman.

Chu (1985; Chu & Ju, 1993) also argues that, although romantic love and compatibility are of paramount importance in mate selection in America, in China such things matter little.

Traditionally, parents and go-betweens arranged young peoples' marriages. Parents' primary concern is not love and compatibility but *men tang hu tui*. Do the families possess the same social status? Are *they* compatible? Will the marriage bring some social or financial advantage to the two families?

On the basis of such testimony, cross-cultural researchers proposed that romantic love would be common only in modern, industrialized countries. It should be less valued in traditional cultures with strong, extended family ties (Simmons, Vom Kolke, & Shimizu, 1986). It should be more common in modern, industrialized countries than in developing countries (Goode, 1959; Rosenblatt, 1967).

In recent years, cultural researchers have begun to test these provocative hypotheses.

RECENT RESEARCH ON CULTURE AND PASSIONATE LOVE

Recently, cultural researchers have begun to investigate the impact (if any) of culture on people's definitions of love, what they desire in romantic partners, their likelihood of falling in love, the intensity of their passion, and their willingness to acquiesce in arranged marriages versus insisting on marrying for love. From this preliminary research, it appears that although the differences cultural theorists have observed do in fact exist, often cultures turn out to be more similar than one might expect. Let us now turn to this research.

The Meaning of Passionate Love

Shaver, Wu, and Schwartz (1991) interviewed young people in America, Italy, and the People's Republic of China about their emotional experiences. They found that Americans and Italians tended to equate love with happiness, and to assume that both passionate and companionate love were intensely positive experiences. Students in Beijing, China, possessed a darker view of love. In the Chinese language, there are few "happy love" words; love is associated with sadness. Not surprisingly, then, the Chinese men and women interviewed by Shaver and his colleagues tended to associate passionate love with ideographic words such as infatuation, unrequited love, nostalgia, and sorrow love.

Other cultural researchers agree that cultural values may indeed, have a profound impact on

the subtle shadings of meaning assigned to the construct of "love" (Cohen, 2001; Kim & Hatfield, 2004; Kitayama, 2002; Luciano, 2003; Nisbett, 2003; Oyserman, Kimmelmeier, & Coon, 2002; Weaver & Ganong, 2004).

There is, however, considerable debate as to how ubiquitous and important such differences are. When social psychologists explored folk conceptions of love in a surprising variety of cultures—including the People's Republic of China, Indonesia, Micronesia, Palau, and Turkey, they found that people in the various cultures possessed surprisingly similar views of love and other "feelings of the heart" (for a review of this research, see K. W. Fischer, Wang, Kennedy, & Cheng, 1998; Jankowiak, 1995; Kim & Hatfield, 2004; Shaver, Murdaya, & Fraley, 2001). In a typical study, for example, Shaver et al. argued that love and "sexual mating, reproduction, parenting, and maintaining relationships with kin and reciprocally altruistic relationships with friends and neighbors are fundamental issues for humans" (pp. 219–220). To test the notion that passionate and companionate love are cultural universals, they conducted a "prototype" study to determine (1) what Indonesian (compared to American) men and women considered to be "basic" emotions, and (2) the meaning they ascribed to these emotions. Starting with 404 Indonesian *perasaan hati* (emotion names or "feelings of the heart") they asked people to sort the words into basic emotion categories. As predicted, the Indonesians came up with the same five emotions that Americans consider to be basic: joy, love, sadness, fear, and anger. Furthermore, when asked about the meanings of "love," Indonesian men and women (like their American counterparts) were able to distinguish passionate love (*asmara*, or sexual desire/arousal) from companionate love (*cinta*, or affection/liking/fondness). There were some differences in the American and Indonesian lexicons, however: "The Indonesian conception of love may place more emphasis on yearning and desire than the American conception, perhaps because the barriers to consummation are more formidable in Indonesia, which is a more traditional and mostly Muslim country" (p. 219).

Much more research needs to be done, of course, before scientists can state this conclusion with any certainty.

Perhaps love is indeed a cultural universal. Or perhaps the times they are "a-changing." One impact of globalization (and the ubiqui-

tous MTV, Hollywood and Bollywood movies, chat rooms, and foreign travel) may be to ensure that when people speak of “passionate love,” they are talking about much the same thing.

What Men and Women Desire in Romantic Partners

Since Darwin’s (1871) classic treatise, *The Descent of Man and Selection in Relation to Sex*, evolutionary theorists have been interested in mate preferences. Many evolutionary psychologists contend that there are cultural universals in what men and women desire in a mate.

This contention is supported by a landmark cross-cultural study conducted by Buss (1994), who asked more than 10,000 men and women from 37 countries to indicate what characteristics they sought in potential mates. These people came from a variety of geographic, cultural, political, ethnic, religious, racial, economic, and linguistic groups. Buss found that, overall, the single trait that men and women in all societies valued most was “mutual attraction–love.” After that, men and women cared next about finding someone who possessed a dependable character, emotional stability and maturity, and a pleasing disposition. Men tended to care more about the physical appearance and youth of their partners than did women; women tended to be more insistent than men that their mates possess high status and the resources necessary to protect themselves and their children.

Buss was interested in cultural and gender universals; nonetheless, he could not help but be struck by the powerful impact that culture had on other mentioned preferences. In China, India, Indonesia, Iran, Israel (the Palestinian Arabs), and Taiwan, for example, young people were insistent that their mate should be “chaste.” In Finland, France, Norway, the Netherlands, Sweden, and West Germany, on the other hand, most judged chastity to be relatively unimportant. A few respondents even jotted notes in the margin of the questionnaire, indicating that, for them, chastity would be a *disadvantage*.

In an alternative analysis of Buss’s (1994) data, Wallen (1989) attempted to determine which was most important—culture or gender—in shaping people’s mate preferences. He found that for some traits—such as good looks and financial prospects—gender had a

great influence on preferences. (Whereas gender accounted for 40–45% of the variance, geographical origin accounted for only 8–17% of the variance.) For other traits, such as chastity, ambition, and preferred age, on the other hand, culture mattered most. (In those instances, gender accounted for only 5–16% of the variance, whereas geographical origin accounted for 38–59% of the variance.) Wallen concluded that, in general, the cultural perspective may well be even more powerful than evolutionary heritage in understanding mate selection.

Cultural researchers provide additional evidence that in different cultural, national, and ethnic groups, people often desire very different things in romantic, sexual, or marital partners. Hatfield and Sprecher (1996), for example, studied three powerful, modern industrial societies—the United States, Russia, and Japan. Men and women in Western, individualistic cultures (e.g., the United States, and to some extent Russia) expected far more from their marriages than did couples in a collectivist culture (e.g., Japan).

As we observed earlier, cultural theorists have predicted that cultural rules should exert a profound impact on the commonness of passionate feelings within a culture, how intensely passion is experienced, and how people attempt to deal with these tumultuous feelings. Alas, the sparse existing data provide only minimal support for this intriguing and plausible-sounding hypothesis.

The Likelihood of Being in Love

Sprecher and her colleagues (1994) interviewed 1,667 men and women in the United States, Russia, and Japan. Based on notions of individualism versus collectivism, the authors predicted that whereas American men and women would be most vulnerable to love, the Japanese would be least likely to be “love besotted.” The authors found that they were wrong. In fact, 59% of American college students, 67% of Russians, and 53% of Japanese students said they were in love at the time of the interview. In all three cultures, men were slightly less likely than were women to be in love. There was no evidence, however, that individualistic cultures breed young men and women who are more love struck than do collectivist societies.

Similarly, surveys of Mexican American, Chinese American, and European American

students have revealed that in a variety of ethnic groups, young men and women show similarly high rates of “being in love” at the present time (Aron & Rodriguez, 1992; Doherty et al., 1994).

The Intensity of Passionate Love

Cultures also seem to share more similarities than differences in the *intensity* of passionate love that people experience. In one study, Hatfield and Rapson (1996) asked men and women of European, Filipino, and Japanese ancestry to complete the PLS. To their surprise, they found that men and women from the various ethnic groups seemed to love with equal passion.

Their results were confirmed in a study done by Doherty and his colleagues (1994) with European Americans, Chinese Americans, Filipino Americans, Japanese Americans, and Pacific Islanders.

LOVE AND MARRIAGE

In the West, before 1700, no society ever equated *le grand passion* with marriage. In the 12th century, in *The Art of Courtly Love*, for example, Andreas Capellanus (1174/1957) stated:

Everybody knows that love can have no place between husband and wife. . . . For what is love but an inordinate desire to receive passionately a furtive and hidden embrace? But what embrace between husband and wife can be furtive, I ask you, since they may be said to belong to each other and may satisfy all of each other's desires without fear that anybody will object? (p. 100)

And Capellanus was not even talking about passionate love—just love. To make his argument perfectly clear, he added: “We declare and we hold as firmly established that love cannot exert its powers between two people who are married to each other” (p. 106).

Shakespeare may have written a handful of romantic comedies in which passionately mismatched couples hurtled toward marriage, but his plays were the exception. Until 1500, most courtly love songs, plays, and stories assumed a darker ending—passionate love was either unrequited, unconsummated, or it spun down to family tragedy and the suicide or deaths of the lovers.

As late as 1540, Alessandro Piccolomini could write peremptorily that “love is a reciprocity of soul and has a different end and obeys different laws from marriage. Hence one should not take the loved one to wife” (Hunt, 1959, p. 206). True to his times, Piccolomini, began to change his mind just before he died.

In the great societies of Asia—China, Japan, and India (lands of arranged marriage)—at least since the end of the 17th century (and thousands of *haiku* poems, *Noh* plays, and heroic legends later), the notion that passionate love and sexual desire go together with thwarted hopes for marriage and suicide has been embedded in the Eastern psyche as an Eternal Truth. Classical tales recount the couple's journey together to the chosen place, leaving forever behind them familiar scenes, agonizing mental conflicts, and the last tender farewells (Mace & Mace, 1980).

To today's young individualistic Americans and Europeans, such tales of forbidden romance may seem ridiculous. But to Asian young romantics, who knew that passion had little chance of flowering into marriage, the tales were sublime tragedies.

In traditional cultures, it was the lovers who had to adapt, not society. Individual happiness mattered little; what was important was the well-being of the family and the maintenance of social order. As one modern Chinese woman asserted: “Marriage is not a relation for personal pleasure, but a contract involving the ancestors, the descendants, and the property” (Mace & Mace, 1980, p. 134).

In contemporary societies, however, both East and West, most young men and women do meet, fall in love, feel sexual desire, and live together or marry. In the next section, we will discuss the revolution that is occurring in the ways young men and women (heterosexual and homosexual) currently select their romantic, sexual, and marital partners. We will see that throughout the world, parental power is crumbling, and that arranged marriages are being replaced by the ideal of love marriages.

Arranged Marriages

Throughout history, cultures have varied markedly in who possessed the power to select romantic, sexual, and marital partners.

As we have seen, in the distant past in most societies, parents, kin, and communities usually had the power to arrange things as they

chose. Marriage was assumed to be an alliance between two *families* (Dion & Dion, 1993; Lee & Stone, 1980). Families might also consult with religious specialists, oracles, and matchmakers (Rosenblatt & Anderson, 1981). When contemplating a union, parents, kin, and their advisors were generally concerned with a number of background questions. What was the young person's caste, status, family background, religion, and economic position? Did his or her family possess any property? How big was the dowry? Would the individual fit in with the entire family? In Indian families, for example, men and women observed that what their families cared most about in arranging a marriage was religion (whether one was a Hindu, Muslim, Sikh, or Christian), social class, education, and family background (Sprecher & Chandak, 1992). If things looked promising, parents and go-betweens began to talk about the exchange of property, dowries, the young couple's future obligations, and living arrangements.

Some problems were serious enough to rule out any thought of marriage. Sometimes religious advisors would chart the couples' horoscopes. Those born under the wrong sign might be forbidden to marry (Bumroongsook, 1992). Generally, young people were forbidden to marry anyone who was too closely related (say, a brother or sister, or a certain kind of cousin). Sometimes, they were forbidden to marry foreigners. (In Thailand, Thais are often forbidden to marry Chinese, Indian, Japanese, Mons, or Malay suitors [Bumroongsook, 1992].)

Similar assets and liabilities have been found to be important in a variety of countries—such as India (Prakasa & Rao, 1979; Sprecher & Chandak, 1992), Japan (Fukuda, 1991), Morocco (Joseph & Joseph, 1987), and Thailand (Bumroongsook, 1992).

Today, in many parts of the world, parents and matchmakers still arrange their children's marriages. Arranged marriages are common in India, in the Muslim countries, in sub-Saharan Africa, and in cultural enclaves throughout the remainder of the world (Rosenblatt & Anderson, 1981).

Compromising on Love

Cross-cultural surveys document the variety of types of mate selection systems that exist throughout the world (Goode, 1963; Goodwin, 1999; Rosenblatt, 1967; Stephens, 1963). These surveys indicate that currently, in most

of the world, prospective brides and grooms, parents, elders, and the extended family consult with one another before arranging a marriage.

The *Ethnographic Atlas* contains anthropological information on more than 1,000 preindustrial societies throughout the world. When Broude and Green (1983) sampled 186 of these groups, they found that in most societies, parents, kin, and young men and women are supposed to consult with one another in this most important of family decisions. In most societies, men have considerably more power than do women to determine their own fates. In only a minority of societies are men and women allowed complete power in choosing their own mates.

Today, even in the most traditional of societies, parents and husbands are generally forced to balance conflicting interests. The Moroccan tribal world, for example, is definitely a man's world. Men possess absolute authority over their wives and children. They possess the power take several wives. They often promise their sons and daughters to potential allies at very young ages. Yet, in families, things do not always happen as they are "supposed" to; men may in theory possess all the power, but in fact they do not. Joseph and Joseph's (1987) vivid descriptions of Moroccan family life make it clear that even in Morocco, compromise is often required. When "all powerful" Moroccan fathers try to force their children into unappealing marriages, sympathetic family members may employ an avalanche of strategies to thwart them. Young lovers may enlist an army of mothers, uncles, brothers, neighbors, and business partners to plead, threaten, and haggle on their behalf. Mothers may warn prospective brides about their sons' "faults." Young men may complain that an undesirable bride is a witch. Young men and women may threaten to kill themselves. Many young men and women rely on witchcraft or magical charms to get their way. Sometimes these desperate stratagems work; sometimes they do not.

Within a single society, arrangements often vary from ethnic group to ethnic group, class to class, region to region, and family to family (Bumroongsook, 1992).

Marriage for Love

In the West, romantic love has long been considered to be the *sine qua non* of marriage (Kelley et al., 1983; Sprecher et al., 1994).

In the mid-1960s, Kephart (1967) asked more than 1,000 American college students: "If a boy (girl) had all the other qualities you desired, would you marry this person if you were not in love with him (her)?" In that era, men and women were found to possess very different ideas as to the importance of romantic love in a marriage. Men considered passion to be essential (only 35% said they would marry someone they did not love). Women were more practical. They claimed that the absence of love would not necessarily deter them from considering marriage (a full 76% admitted they would be willing to marry someone they did not love). Kephart suggested that whereas men might have the luxury of marrying for love, women did not. A woman's status was dependent on that of her husband; thus, she had to be practical and take a potential mate's family background, professional status, and income into account.

Since the 1960s, sociologists have continued to ask young American men and women about the importance of romantic love. They have found that, year by year, young American men and women increasingly value and demand more and more of love. In the most recent research, 86% of American men and a full 91% of American women answered the question of whether they would wed without love with a resounding "No!" (Allgeier & Wiederman, 1991). Obviously, in the West, romantic love *is* considered to be a prerequisite for marriage. Today, American men and women assume that romantic love is so important, they claim that if they fell out of love, they would not even consider *staying* married (Simpson, Campbell, & Berscheid, 1986)! Some social commentators have suggested that with more experience, these young romantics might find that they are willing to "settle" for less than they think they would, but as of yet there is no evidence to indicate that this is so.

How do young men and women in other countries feel about this issue? Many cultural psychologists have pointed out that cultural values have a profound impact on how people feel about the wisdom of love matches versus arranged marriages.

Throughout the world, arranged marriages are still relatively common. It seems reasonable to argue that in societies such as China (Pimentel, 2000; Xu & Whyte, 1990), India (Sprecher & Chandak, 1992), and Japan (Sprecher et al., 1994), where arranged marriages are fairly typical, they ought to be

viewed more positively than in the West, where they are relatively rare.

To test this notion, Sprecher and her colleagues (1994), asked American, Russian, and Japanese students: "If a person had all the other qualities you desired, would you marry him or her if you were not in love?" (Students could answer only "yes" or "no.") The authors assumed that only Americans would demand love *and* marriage; they predicted that both the Russians and the Japanese would be more practical. They were wrong! Both the Americans and the Japanese were romantics. Few of them would consider marrying someone they did not love (only 11% of Americans and 18% of the Japanese said "yes"). The Russians were more practical; 37% said they would accept such a proposal. Russian *men* were only slightly more practical than men in other countries. It was the Russian *women* who were most likely to "settle."

Despite the larger proportion of Russian women willing to enter a loveless marriage, a large majority of individuals in the three cultures would refuse to marry someone they did not love.

Similarly, in a landmark study, Levine, Sato, Hashimoto, and Verma (1995) asked college students in 11 different nations if they would be willing to marry someone they did not love, even if that person had all the other qualities they desired. (Students could answer "yes," "no," or admit that they were "undecided"). In affluent nations such as the United States, Brazil, Australia, Japan, and England, young people were insistent on love as a prerequisite for marriage. Only in traditional, collectivist, undeveloped nations, such as the Philippines, Thailand, India, and Pakistan, were students willing to compromise and marry someone they did not love. In these societies, of course, the extended family is still extremely important and poverty is widespread.

Research suggests that, today, young men and women in many countries throughout the world consider love to be a prerequisite for courtship and marriage. It is primarily in Eastern, collectivist, and poorer countries that passionate love remains a bit of a luxury.

HOW LONG DOES PASSIONATE LOVE LAST?

Passion sometimes burns itself out. Consider this exchange between anthropologist Shostak (1981) and a !Kung (African) tribesman as they

observed a young married couple, running after each other:

As I stood watching, I noticed the young man sitting in the shade of a tree, also watching. I said, "They're very much in love, aren't they?" He answered, "Yes, they are." After a pause, he added, "For now." I asked him to explain, and he said, "When two people are first together, their hearts are on fire and their passion is very great. After a while, the fire cools and that's how it stays." . . . "They continue to love each other, but it's in a different way—warm and dependable." . . . How long did this take? "It varies among couples. A few months, usually; sometimes longer. But it always happens." Was it also true for a lover? "No," he explained, "feelings for a lover stay intense much longer, sometimes for years." (p. 268)

Fisher (2004) argues that the transient nature of passionate love is a cultural universal. She believes that our *Homo sapiens* ancestors experienced passionate love and sexual desire for very practical genetic reasons. Our hominid ancestors were primed to fall ardently, sexually in love for about 4 years. This is precisely the amount of time it takes to conceive a child and take care of it until it is old enough to survive on its own. (In tribal societies, children are relatively self-sufficient by this age. By this time, they generally prefer to spend most of their time playing with other children.) Once our ancestors no longer had a practical reason to remain together, they had every evolutionary reason to fall out of love with their previous partner and to fall in love with someone new. Why were people programmed to engage in such serial pair-bonding? Fisher maintained that such serial monogamy produces maximum genetic diversity, which is an evolutionary advantage. To test her hypothesis that, generally, love is fleeting, Fisher (1989) examined the divorce rates in collecting/hunting, agricultural, pastoral, fishing, and industrial societies, scouring ethnographic records and the *Demographic Yearbooks* of the United Nations. She found that, as predicted, throughout the world, couples most commonly divorced in their fourth year of marriage. She argues that, today, the same evolutionary forces that influenced our ancestors shape the modern cross-cultural pattern of marriage–divorce–remarriage. Fisher's ideas are stimulating, but her exclusion of cultural forces considering their omnipresence in nearly all matters related to love and sex, mandate a certain skepticism on the part of the reader.

THE DARK SIDE OF PASSIONATE LOVE: JEALOUSY

What is jealousy? Social commentators have argued that jealousy consists of two basic components: bruised pride and indignation at the violation of one's property rights.

Anthropologist Mead (1931) contended that jealousy is really little more than wounded pride. The more shaky one's self-esteem, the more vulnerable one is to jealousy's pangs. She observed: "Jealousy is not a barometer by which depth of love can be read. It merely records the degree of the lover's insecurity. . . . It is a negative, miserable state of feeling, having its origin in the sense of insecurity and inferiority" (pp. 120–121). Researchers in the United States, Israel, and the Netherlands have found that people with low self-esteem *are* especially susceptible to jealousy (Bingle & Buunk, 1986; Nadler & Dotan, 1992; White & Mullen, 1989).

The French philosopher René Descartes, writing in the early 17th century, defined jealousy as "a kind of fear related to a desire to preserve a possession (cited in Davis, 1948/1977, p. 129). Researchers in several countries have found that a loss—whether one thinks of one's romantic partner or mate as a beloved person or a mere possession—can stir up jealousy (White & Mullen, 1989). Researchers in Israel (Nadler & Dotan, 1992) and the Netherlands (Bingle & Buunk, 1986) found that individuals experience the most jealousy and the most severe physiological reactions (trembling, increased pulse rate, nausea), when an affair poses a serious threat to their dating or marital relationship.

Berscheid and Fei (1977) provide evidence that both factors (low self-esteem and the fear of loss) are important in fueling jealous passion. They found that the more insecure men and women are, the more dependent they are on their romantic partners and mates, and the more seriously their relationship is threatened, the more fierce their jealousy.

Gender Differences in Jealousy: Evolutionary Theory

What Makes Men and Women Jealous?

Evolutionary psychologists such as Buss (1994), Tooby and Cosmides (1992), and Wilson and Daly (1992) argue that "the specifics of evolutionary biology have a central significance for understanding human thought and action. Evolutionary processes are the "archi-

tect” that assembled, detail by detail, our evolved psychological and physiological architecture” (Tooby & Cosmides, 1992, p. 19).

In attempting to understand cultural differences and the factors that predispose cultures to view love and emotional and sexual fidelity as more or less essential, we would do well to look to mankind’s evolutionary heritage and the adaptive problems our ancestors attempted to solve by devising jealousy.

For example, according to Buss (1994), in the course of evolution, men and women have been programmed to differ markedly in the kinds of things that incite jealousy. Men can never know for sure whether the children they *think* are theirs (and in which they choose to invest their all), are really their own. Thus, men should find sexual infidelity the most worrying. Women, on the other hand, know that any children they conceive are theirs. Thus, they should care far less about their mates’ sexual liaisons. What worries *them* is the possibility that their mates may be forming a *deep, emotional attachment* to a rival and squandering scarce resources on another.

As Wilson and Daly (1992) observed:

In the case of *Homo sapiens*, parental investments are often substantial, including allocations of time and effort and transfers of resources over the course of decades. Thus a major threat to a man’s fitness is the possibility that his mate may become pregnant by another man, especially if the cuckold should fail to detect the fact and invest in the child as his own. If there is a corresponding threat to a woman’s fitness . . . it is that her mate will channel resources to other women and their children. It follows that men’s and women’s proprietary feelings toward their mates are likely to have evolved to be qualitatively different, men being more intensely concerned with sexual infidelity per se and women being more intensely concerned with the allocation of their mates’ resources and attentions. (p. 292)

Scientists have also collected sparse evidence that in men, cuckoldry and sexual infidelity incite the most jealousy, while in women, it is their husbands’ spending time talking and sharing common interests or resources with other women that is most upsetting (Buss & Schmitt, 1993; Glass & Wright, 1985).

How Do Men and Women React to Jealous Provocations?

Researchers have found that men and women may react in somewhat different ways to jeal-

ous provocation. Israeli psychologists Nadler and Dotan (1992), for example, found that when jealous, men tend to concentrate on shoring up their sagging self-esteem. Jealous women are more likely to try to do something to strengthen the relationship. Bryson (1977) speculated that these gender differences may well be due to the fact that most societies are patriarchal. It is acceptable for men to initiate relationships. Thus, when men are threatened, they can easily go elsewhere. Women do not have the same freedom. Therefore, they devote their energies to keeping the relationship from foundering. Studies in a variety of countries—including Israel (Nadler & Dotan, 1992) and the Netherlands (Buunk, 1982)—have found that these same gender differences exist in many parts of the world.

Alas, when Harris (2003) conducted a “meta-analysis” of more than 100 studies designed to determine whether there were gender differences in what sparked jealousy, she found little support for this contention. Harris reviewed men’s and women’s self-reports and psychophysiological reactions, as well as data on morbid jealousy, spousal abuse, and jealousy-inspired homicides in a variety of jealousy provoking situations. In summarizing this voluminous research, she was forced to conclude: “The results provide little support for the claim that men and women are innately wired to be differentially upset by emotional and sexual infidelity” (p. 117). Jankowiak (1995) agrees. He argues that men and women in all cultures find both emotional and sexual infidelity extremely upsetting. It is male power, he contends, not innate gender differences, that accounts for differences in men’s and women’s willingness to express their jealous feelings.

In attempting to explain why there might *not* be a dimorphic sexual jealousy mechanism, Harris (2003) makes two important points: (1) Our ancestral past may have been significantly different from the one envisioned by evolutionary theorists; and (2) even if the adaptive problems were as described, more *general* jealousy mechanisms may have been selected for, rather than the hardwired *specific module* postulated.

Alas, there exists no spaceship that will allow scientists to travel back to the Pleistocene, so we can observe how our hunter-gather forebears lived. In part, we scholars are forced to make up “just so” stories about the past—plausible stories, to be sure, but stories nonetheless. In fact, evolutionary theorists *have* postulated many alternative views of love relation-

ships during the Pleistocene, including the following ideas: (1) That men invested very little in child rearing, versus (2) a significant paternal involvement in childbearing was a key factor in determining the number of viable offspring that lived to reproduce; thus, men were motivated to devote a great deal of time, energy, and resources to child rearing. Harris (2003) lists a number of these possibilities. If the Pleistocene adaptive solutions were different than those we currently envision, then they would, of course, lead to different cognitive structures in today's men and women. Only if cultural and evolutionary theorists work hand in hand will scientists be able to develop compelling theories of human behavior—theories that respect both the “architecture” of the past and the cultural challenges to be met by men and women of the future.

Let us now turn to some of the discoveries of cultural theorists in the area of jealousy.

Cultural Differences in Jealousy

Anthropologists have noted that cultures differ markedly in what sets off jealousy, in how jealous people get, and in whether they have the power to do anything about it (Hupka & Ryan, 1990; Hupka, 1991).

What Sparks Jealousy?

Men and women use a number of clues to tell them that someone they love is drifting away. Hupka (1981) illustrated the point that cultures define very different things as threats to self-esteem, relationships, and property with the following scenario:

On her return trip from the local watering well, a married woman is asked for a cup of water by a male resident of the village. Her husband, resting on the porch of their dwelling, observes his wife giving the man a cup of water. Subsequently, they approach the husband and the three of them enjoy a lively and friendly conversation into the late evening hours. Eventually the husband puts out the lamp, and the guest has sexual intercourse with the wife. The next morning the husband leaves the house early in order to catch fish for breakfast. Upon his return he finds his wife having sex again with the guest. The husband becomes violently enraged and mortally stabs the guest.

At what point in the vignette may one expect the husband to be jealous? It depends, of course, in which culture we place the husband. A husband

of the Pawnee Indian tribe in the 19th century bewitched any man who dared to request a cup of water from his wife. . . . An Ammassalik Eskimo husband, on the other hand, offered his wife to a guest by means of the culturally sanctioned game of “putting out the lamp.” A good host was expected to turn out the lamp at night, as an invitation for the guest to have sexual intercourse with the wife. The Ammassalik, however, became intensely jealous when his wife copulated with a guest in circumstances other than the lamp game or without a mutual agreement between two families to exchange mates, and it was not unusual for the husband to kill the interloper.

The Toda of Southern India, who were primarily polyandrous at the turn of the century . . . would consider the sequence of events described in the vignette to be perfectly normal. That is to say, the husband would not have been upset to find his wife having sexual relations again in the morning if the man were her *mokbthodvaioi*. The Todas had the custom of *mokbthoditi* which allowed husbands and wives to take on lovers. When, for instance, a man wanted someone else's wife as a lover he sought the consent of the wife and her husband or husbands. If consent was given by all, the men negotiated for the annual fee to be received by the husband(s). The woman then lived with the man just as if she were his real wife. Or more commonly, the man visited the woman at the house of her husband(s).

It is evident from these illustrations that the culture of a society is a more potent variable than characteristics of the individual in predicting which events someone will evaluate as a threat. (pp. 324–325)

Buunk and Hupka (1987) found that there are also cultural differences in the kinds of things that trigger jealousy in modern, industrialized nations. They interviewed 2,079 college students from seven industrialized nations—the United States, Hungary, Ireland, Mexico, the Netherlands, the Soviet Union, and Yugoslavia (the Soviet Union and Yugoslavia no longer exist as nations). Students were asked to take a look at several statements: *flirting* (“It does not bother me when I see my lover flirting with someone else”); *kissing* (“When I see my lover kissing someone else, my stomach knots up”); *dancing* (“When my lover dances with someone else, I feel very uneasy”); *hugging* (“When somebody hugs my lover, I get sick inside”); *sexual relationships* (“It would bother me if my partner frequently had satisfying sexual relations with someone else”); and *sexual fantasy* (“It is entertaining to hear the sexual fantasies my partner has about another per-

son”). They were then asked to indicate to what extent they agreed with each of these statements.

There were some striking cross-national similarities in the kinds of things that people found threatening or nonthreatening. Behaviors such as dancing, hugging, and talking about sexual fantasies were taken in stride. Explicit erotic behavior—flirting, kissing, or having sexual relations with someone else—evoked strong jealousy.

There were some striking cultural differences in *exactly* what people found upsetting, however. United States citizens for example, took “hugging” for granted. They were about average in how upsetting they found the other activities to be. In the Netherlands, kissing, hugging, and dancing evoked less jealousy than in most other countries, but citizens got more upset by the idea of their partner’s having sexual fantasies about other people than did others. In Yugoslavia, flirting evoked a more negative emotional response than in any other country, but citizens were least concerned about sexual fantasies or kissing. Hungarians found both hugging and kissing most provoking. Citizens from the Soviet Union were upset by dancing and sexual relations.

The next step, Buunk and Hupka (1987) observed, is to find out why such cultural and cross-national differences exist.

Intensity of Jealousy

Hupka and Ryan (1990; Hupka, 1991) argued that a culture’s social structure should have a marked impact on how vulnerable its members are to jealousy. Consider two tribes: the Ammassalik Eskimos (known for their extreme jealousy) and the Toda tribe of India (known for their startling lack of jealousy). The Ammassalik Eskimo family had to be completely self-sufficient (Mirsky, 1937). Each couple had to produce everything that they needed to survive—shelter, clothing, food, and utensils. Loners rarely survived the long, harsh Arctic winters. It is not surprising to discover that the Ammassalik were eager, if not desperate, to find a competent mate. No wonder that those who did had problems with jealousy. A passionate rival was literally a threat to survival.

The Todas of India, on the other hand, had a clan economy (Rivers, 1906). Marriage was a luxury, not a necessity. (The most common form of marriage was fraternal polyandry:

When a woman married, she became the wife of all her husband’s brothers.) Not surprisingly, people did not distinguish much between their own children and those of other tribesmen (of course, men had no way of knowing who was the father of “their” children). Companions for friendship and for sex were easy to find. The clan worked together on most tasks and shared everything. The idea of “private” property did not really exist. Not surprisingly, in this society, jealousy was rare.

Hupka and Ryan (1990) argued that there is a simple explanation for such findings. In any culture, the greater the importance of marriage and private property, the more the marital partners are jealous of potential romantic rivals. To test this notion, the authors selected 150 tribal societies from those described in the Human Relations Area Files. The scientists then classified societies’ political and economic customs: How important was it to be married? (Was it, for example, necessary for survival?) How easy was it to find sex outside of marriage? How important was private property? (Was everything owned in common? Privately owned? Was theft punished?) How important was it to have children?

Next, the authors coded the extent of jealousy in each society. In some, men generally had little reaction when they heard their mates had been unfaithful. In others, such as the Maori of New Zealand (Mishkin, 1937), husbands demanded money or valuable property from their wives’ lovers. If a Bakongo adulterer could not pay the compensation, he had to work the husband’s fields, as well as his own. This generally ensured that he would be too exhausted to chase women (White & Mullen, 1989). In other cultures, infidelity was cause for separation or divorce. In some, the adulterous spouse or rival was banished or killed. For example, the ancient Hebrews would stone to death a married woman and her lover if the affair took place in the city. In the country, it was assumed that the woman had been raped but no one had heard her screams; hence, only the man was killed (Murstein, 1974).

The authors found that culture, and the severity of the threat² that adultery posed in that culture, had a powerful impact on how men reacted to their wives’ adultery. It was culture, not genes, that determined the nature of men’s response to news that their wives were having an affair. Would they react with a shrug, with indignation, or with murderous violence? Much depended on the place they called home.

The data also highlighted the importance of power in determining how people respond to jealous provocations. In most tribes, women, who were usually physically weaker than men, had less political and economic power. Although neither men nor women liked infidelity, only the men were in a position to do much about it. In general, women were "supposed" to respond to adultery with only the gentlest forms of aggression. They could express righteous indignation, cry, threaten to walk out, or divorce. The men were allowed to bring out the really big guns: when offended, to banish or murder their mates.

How the Jealous React

Salovey and Rodin (1985) surveyed 25,000 Americans (heterosexual, bisexual, and homosexual) from a variety of ethnic groups. How had they reacted the last time they were jealous? Although men and women differed little, heterosexuals (possibly because of their views of commitment) had a more passionate reaction than did their gay, lesbian, or bisexual peers to provocation. Whatever their gender and orientation, however, jealous lovers described a variety of jealous behaviors: They became obsessed with painful images of their beloved in the arms of their rivals. They sought out confirmation of their worst fears. They searched through their partners' personal belongings for unfamiliar names and telephone numbers. They telephoned their mates unexpectedly, just to see whether they were where they had said they would be. They listened in on their telephone conversations and followed them. They gave their mates the third degree about previous or present romantic relationships.

Anthropologists find that people throughout the world engage in similar kinds of detective work: The Dobuan husband watches his wife while she works the fields and counts her footsteps if she goes into the bush. Too many footsteps mean a possibility of a secret sexual liaison (Mead, 1931). Apache men who leave their encampment generally ask their close blood relatives to spy on their wives (Goodwin, 1942). White and Mullen (1989) found that people try to cope with their jealous feelings, the threats to their self-esteem, and their fears of loss in a variety of ways: Sometimes lovers refuse to see what they do not want to see. Some jealous lovers focus on *themselves*.

"What's wrong with me?" or "What did I do wrong?" they ask. Once they spot "the problem," they set out to try to make themselves more appealing. Other people focus on controlling *their mates*. In Medieval times, British and European nobility locked their wives up in chastity belts while they were off at the Crusades. Other cultures have relied on infibulation (stitching together the labia majora), vaginal plugs, and clitoridectomy (a form of female castration designed to eliminate sexual pleasure), to keep women in check (Daly, Wilson, & Weghorst, 1982). Other lovers focus on eliminating *the rival*.

Eventually, in most societies, most people give up. If the relationship really is over, they recognize it and try to get on with their lives.

Vengeance

Of course, some jealous lovers react more violently. In the 17th century, Burton (1621/1927) wrote in *The Anatomy of Melancholy* that "those which are jealous proceed from suspicion to hatred; from hatred to frenzie; from frenzie to injurie, murder and despair" (p. 428). Historically, since men had the most power, they were allowed to let their "frenzie" lead to murder. Women had to be content with more tepid responses.

Arapaho (Native American) men might beat wives they suspected of having sexual relations with anyone else:

Occasionally a suspicious man calmly sent his wife away, either to her paramour or to her home. More often he became angry and jealous. Usually he whipped her, and cut off the tip of her nose or her braids, or both. According to Kroeber . . . he also slashed her cheeks. This treatment of an unfaithful wife was conventional and neither her parents nor the tribe did anything about it. (Hilger, 1952, p. 212)

The king of the Plateau tribes of Zimbabwe executed men caught with any of his wives. The wives were grossly mutilated (Gouldsbury & Sheane, 1911). In earlier times, Apache husbands also killed their rivals and mutilated their wives (by cutting off the end of their noses); presumably, that made them less appealing the next time (G. Goodwin, 1942).

In Western cultures, men are far more likely to beat or murder their girlfriends and wives than their rivals (White & Mullen, 1989). Today, in America, family peace centers report

that about two-thirds of wives who are forced to seek shelter do so because their husbands' excessive or unwarranted jealousy has led them to repeatedly assault the women (Gayford, 1979). Male jealousy is the leading cause of wife battering and homicide worldwide (Buss, 1994; Daly & Wilson, 1988a, 1988b).

In the West, until recently, such vengeance was approved or treated leniently. The 18th-century English jurist Blackstone commented that killing in a situation where a man or woman is caught in the act "is of the lowest degree of manslaughter; . . . for there could not be a greater provocation" (quoted in Smith & Hogan, 1983, p. 288).

In many countries, the courts have been sympathetic to such "crimes of passion." Traditionally, it was considered to be a man's right to defend his "honor." In Morocco, for example, the law excuses killing one's wife if she is caught in the act of adultery, but a woman would not be excused for killing her husband in the same circumstances (Greenhouse, 1994). In São Paulo (Brazil's most populous city), in 1980–1981, 722 men claimed "defense of honor" for murdering their wives. Brazilian women adopted the slogan "Lovers don't kill," and campaigned against allowing such a defense in murder trials. Once again, we see that, worldwide, the times they are a changing (see Brooke, 1991, for a discussion of the changes globalization has brought to views of "honor" and crimes of violence in one culture—Brazil).

IN CONCLUSION

The preceding studies, then, suggest that the large differences that once existed between Westernized, modern, urban, industrial societies and Eastern, modern, urban industrial societies may be fast disappearing. Those interested in cross-cultural differences may be forced to search for large differences in only the most underdeveloped, developing, and collectivist of societies—such as in Africa or Latin America, in China or the Arab countries (Egypt, Kuwait, Lebanon, Libya, Saudi Arabia, Iraq, or the United Arab Emirates).

However, it may well be that even there, the winds of Westernization, individualism, and social change are blowing. In spite of the censure of their elders, in a variety of traditional cultures, young people are increasingly adopting "Western" patterns—placing a high value

on "falling in love," pressing for gender equality in love and sex, and insisting on marrying for love (as opposed to arranged marriages). Such changes have been documented in Finland, Estonia, and Russia (Haavio-Mannila & Kontula, 2003), as well as among Australian aboriginal people of Mangrove and a Copper Inuit Alaskan Indian tribe (see Jankowiak, 1995, for an extensive review of this research).

Naturally, cultural differences still exert a profound influence on young people's attitudes, emotions, and behavior, and such differences are not likely to disappear in our lifetime. In Morocco, for example, marriage was once an alliance between families (as it was in most of the world before the 18th century,) in which children had little or no say. Today, although parents can no longer simply dictate whom their children will marry, parental approval remains critically important. Important though it is, however, young men and women are at least allowed to have their say (see D. A. Davis & Davis, 1995).

Many have observed that, today, two powerful forces—globalization and cultural pride/identification with one's country (what historians call "nationalism")—are contending for men's and women's souls. True, to some extent, the world's citizens may to some extent be becoming "one," but in truth, the delightful and divisive cultural variations that have made our world such an interesting and simultaneously dangerous place, are likely to add spice to that heady brew of love and sexual practices for some time to come. The convergence of cultures around the world may be reducing the differences in the ways passionate love is experienced and expressed in our world, but tradition can be tenacious, and the global future of passionate love cannot be predicted with any certainty.

NOTES

1. Supporting the contention that prehistoric people were monogamous is the fact that today men and women are fairly similar in size. Supporting the contention (more strongly) that our ancestors were polygamous are the following: (1) Men are generally taller and stronger than are women; (2) because selection is based on physical strength and body mass, not sperm competition, men's testes are fairly small; (3) women do not possess sexual swellings; and (4) sexual intercourse can last fairly long, because there are not many rivals competing for access.

2. The authors judged sexual dalliance to be most threatening if in that culture (1) marriage was required for companionship, status, or survival; (2) it was difficult to find sex outside of marriage; (3) property is privately owned; and (4) it was important to have children.

CHAPTER 32

Emotion, Biology, and Culture

ROBERT W. LEVENSON
JOSE SOTO
NNAMDI POLE

In this chapter we first review theories of emotion that are most relevant to a consideration of the roles of biology and culture. We then review the existing cross-cultural and cross-ethnic research relevant to these theories, with particular emphasis on studies that have actually measured biological responses that occur during emotional reactions. We conclude by presenting a revised version of our earlier biocultural model of emotion (Levenson, 2003) that allows for both biological and cultural influences, and that is informed by existing empirical data.

EMOTION THEORY

Emotions are short-lived psychological-physiological phenomena that represent efficient modes of adaptation to changing environmental demands (Levenson, 1994). In humans, the emotion system is influenced by both biology (e.g., the availability of a facial musculature that can produce an array of appearance changes) and culture (e.g., the rules, traditions, and beliefs concerning how and when to use these muscles to reveal or conceal how we feel).

Emotion theorists have long struggled with how to account for both kinds of influence. In general, theories growing out of the evolutionary tradition embrace biological influences, viewing specific features of the emotion system as chosen by natural selection for their value in survival and reproduction. In contrast, theories growing out of the anthropological tradition embrace cultural influences, viewing emotion as created in ways that meet cultural traditions, beliefs, and values. Although most modern theories eschew extreme evolutionary and cultural construction positions, they differ greatly in terms of how they locate emotion between these poles.

Evolutionary Theories

Darwin pioneered the evolutionary view of emotions in his book *The Expression of the Emotions in Man and Animals* (1872), portraying emotional expression as a hardwired, automatic response that is integrally tied to the nervous system. A large part of his research program was devoted to documenting the existence of emotional facial expressions and gestures that were common across cultures and

species—that is, to demonstrating the universality of emotional expression. Interestingly, despite recognizing the important communicative functions of emotional expression, he never focused on how individuals label their emotions. This likely reflected his commitment to a cross-species approach. Although not totally discounting the role of culture in emotion, Darwin did not afford it great importance.

Physiological Theories

Near the turn of the century, two influential theories arose that emphasized the critical role that physiological responses played in emotion. James (1884) suggested that emotions derive from the body's patterned response to challenging situations (e.g., "I feel afraid because I am trembling"). This peripheralist view envisioned autonomic and somatic nervous system activity as antecedents rather than as consequences of emotion. Cannon (1927) took a different view, believing that emotions originate in the central nervous system, with the resulting emotional experience growing out of unconscious neurological activity. Although differing in their views as to the source of emotion and the role of conscious awareness, both approaches viewed physiological changes as primary determinants of emotion. Facial expressions were not explicitly considered by James or Cannon, and neither theory was very conducive to cultural influence.

Schachter and Singer (1962) proposed another physiologically based theory of emotion that was far more amenable to cultural influence. In their view, the physiological arousal associated with emotion is essentially undifferentiated. The individual perceives this arousal and labels it as a particular emotion based on a cognitive appraisal of the current situation. From this perspective, physiology is integral to emotion, but the appraisal process is key to determining the specific emotion that occurred. Although Schachter and Singer did not explore cultural influences in any depth, their appraisal process certainly allows for culturally determined variation in how the meaning of a given situation is understood.

Social Construction Theories

In *Sex and Temperament in Three Primitive Societies* (1935), anthropologist Mead wrote: "We are forced to conclude that human nature

is almost unbelievably malleable, responding accurately and contrastingly to contrasting cultural conditions" (p. 289). This view represents one of the earliest social constructivist theories of emotion, envisioning emotions as arising from the dynamic interactions between individuals and cultures (Lutz & Abu-Lughod, 1990; Oatley, 1993; Saarni, 1993). To explicate this perspective, Oatley (1993) likens emotions to language:

Although there is no doubt a common basis for language in all human beings, each culture has its own vocabulary, its syntactic forms, its meanings, and its range of pragmatic effects. Comparably, it is argued, that each culture has patterns of emotions that are somewhat distinctive, that derive from social practices, and that convey meanings and effects to members of that culture. (p. 341)

In sharp contrast to the theories of Darwin, James, and Cannon, social constructivists locate the core of emotion outside of the human body and squarely within cultural processes. Although some theorists in this tradition acknowledge a few innate emotional responses, they still maintain that most aspects of emotion are socially constructed. Because cultural influences have their effect on emotion over time, social constructionists often adopt a developmental view of emotion, emphasizing that emotions are socialized from childhood on (e.g., Saarni, 1993).

Lexical Theories

Lexical theorists highlight the role of language in emotion, believing that emotion is "created in, rather than shaped by, speech in the sense that it is postulated as an entity in language where its meaning to social actors is also elaborated" (Lutz & Abu-Lughod, 1990, p. 12). From this perspective, the essence of emotion lies in the ways that people label their subjective experience. For example, claims of universality for a given emotion would require it to have lexical equivalents in all natural languages:

If lists [of emotion terms] . . . are supposed to enumerate universal human emotions, how is it that these emotions are so neatly identified by means of English words? For example, Polish does not have a word corresponding exactly to the English word disgust. What if the psychologists working

on the “fundamental human emotions” happened to be native speakers of Polish rather than English? Would it still have occurred to them to include “disgust” on their list? (Wierzbicka, 1986, p. 584)

Lexical theorists raise important methodological caveats for emotion research. For example, to get around the problem of translation equivalents between languages, Wierzbicka (1986) has advocated using “language-independent semantic metalanguage” (e.g., replacing the term *fear* with “the experience that occurs when one thinks that something bad might happen to one”). Ascribing such a key role for language in emotion provides for profound cultural influence in the ways that emotions are labeled and experienced. Lexical theories have not envisioned a major role for biological factors such as facial expression.

Appraisal Theories

Appraisal theories are based on the notion that emotions result from our conscious or unconscious cognitive evaluations of events and situations. Placing the emphasis on appraisal allows for cross-cultural and within-cultural variability in the evaluative process, without precluding some universality in biological features. In these models, subjective emotional experience is largely dependent on earlier evaluative processes: Physiological and facial reactions follow as a natural response to the felt emotion. Appraisal theories readily encompass cultural influences on emotion in terms of differences in the ways particular situations are appraised. As Scherer (2000) notes:

Component theorists share the social constructivists’ insistence on the powerful role of sociocultural determinants of emotional experiences by assuming, for example, that cultural values can strongly affect appraisal, that the regulation of the emotion depends on norms and social context, and that the subjective experience reflects the sociocultural context. (p. 152)

At the same time, these theorists are often quite comfortable with indications that a particular biological aspect of emotion (e.g., physical sensations) shows consistency across cultures (Scherer & Wallbott, 1994).

Biocultural Theories

A number of emotion theorists have attempted to integrate the roles of biology and culture, seeing both as significantly influencing emotion. In a summary of biocultural approaches to emotion, Hinton (1999) outlined four kinds of integrative theories: (1) biocultural synergy, (2) embodiment, (3) systems theory, and (4) local biology. Biocultural synergy theorists argue that biology and culture are mutually dependent and continually transform each other throughout the organism’s lifetime (Changeux, 1985). Embodiment represents the commingling of physiological and mental processes, and asserts that emotion cannot be understood in isolation from the social context in which it occurs. Systems theory envisions emotions as comprising multiple components, including biology and culture, that work in parallel and are all necessary for understanding emotion. Local biology highlights the interplay between biology and culture over the lifetime of the organism and allows for the creation of new variations in the emotional system that arise from this codevelopment. At the core of these anthropologically based theories is an equal partnership between culture and biology. However, they are often articulated at a very broad level and do not specify precisely how culture and biology interact to produce the various aspects of emotion, such as facial expression, subjective experience, and peripheral physiological response. An exception to this is Ekman’s “neurocultural” theory (Ekman & Friesen, 1969), which describes how emotional facial expression can have both universal features (e.g., facial configurations associated with particular emotions) and culture-specific features (e.g., “display rules” concerning when these facial configurations are shown or hidden). At the end of this chapter, we present an elaboration of our own biocultural model of emotion (Levenson, 2003), which encompasses multiple aspects of emotion and allows for different “mixtures” of biological and cultural influences.

Summary

Emotion theories run the gamut from those that view emotion as purely biological to those that envision pure cultural construction. Many theories, especially the more contemporary

ones, fall between these extremes, proposing different mixtures of biological and cultural influences, different ways that these two forces interact, and different implications for the nature of emotion.

EMPIRICAL STUDIES

In this section, we examine the empirical evidence relevant to the question of whether emotions manifest themselves differently across cultures, concentrating on two biological systems prominent in emotion: facial expression and peripheral physiology. The focus of this review is on studies of emotion *production* (in which emotions are stimulated in some way and responses in these two biological systems are measured). We mention only in passing the literature on cultural influences on emotion *recognition* (in which subjects typically are asked to identify the emotion portrayed in photographs; see Elfenbein & Ambady, 2002, for a review) and on emotion-related *psychopathologies* (e.g., Pole, Best, Metzler, & Marmar, 2005; Tsai, Pole, Levenson, & Muñoz, 2003). This distinction among emotion production, emotion recognition, and emotion pathology reflects our view that these are quite different processes and are likely influenced by culture in different ways. Of the three processes, emotion production is arguably the most elemental stage upon which the intricate dance between biology and culture is performed.

Facial Expression

Given the apparent differences in facial features between ethnocultural groups, one might wonder whether their facial expressions of emotions also differ. Darwin (1872) was one of the first to examine whether facial expressions of emotions were culturally invariant. Surveying former British residents living in approximately 40 regions of the world, he found that the expressions of what are often referred to as “basic” emotions (e.g., anger, disgust, fear, happiness, sadness, surprise) were observed in all. Although his methods were crude by modern standards, this work set the stage for future studies using improved methodologies. These subsequent studies also found evidence that the basic emotions are associated with similar facial expressions in different

ethnocultural groups. For example, Ekman (reviewed in 1982) presented members of a preliterate culture in New Guinea with situations thought to elicit anger, disgust, fear, happiness, sadness, and surprise, and asked them to display the appropriate facial expression. Videotapes of these expressions were later shown to American college students, who correctly identified the emotions displayed by the New Guineans. This result suggests that facial expressions associated with these emotions are sufficiently similar in these two cultures to allow for “translation” and “backtranslation.” Although there has been a great deal of controversy over how definitive the evidence is for the universality of the *recognition* of emotional facial expression (Ekman, 1994; Russell, 1994), there is certainly no consistent evidence suggesting that some cultures rewrite the basic mapping between facial expression and emotion (e.g., cultures in which happiness is associated with lowered rather than raised lip corners).

Cultural differences have been found in the *amount* and *type* of emotion shown in response to a given elicitor. Comparing two cultures, Tsai and Chentsova-Dutton (2003) found that European Americans of Scandinavian descent showed less emotional facial behavior (especially during happiness and love memories) than those of Irish descent. These findings were interpreted as reflecting the cultural traditions of emotional control in Scandinavian culture and of emotional expression in Irish culture. However, not all studies have found cultural differences. Tsai, Levenson, and Carstensen (2000) found no differences in emotional facial expressions of young and elderly Chinese American and European American participants in response to film clips designed to elicit amusement or sadness.

Comparing acculturation levels in Chinese Americans and Mexican Americans, Soto, Levenson, and Ebling (2005) found that emotional facial behavior in response to an aversive, acoustical startle stimulus mirrored ethnographic norms to the extent that participants identified strongly with their culture of origin. Specifically, they found less negative emotional expression in Chinese Americans most identified with Chinese culture (which emphasizes emotion moderation) and more negative emotional expression in Mexican Americans most identified with Mexican cul-

ture (which emphasizes emotion expression). Similarly, Tsai, Chentsova-Dutton, Freire-Bebeau, and Przymus (2002) found that Hmong Americans who were most strongly identified with Hmong culture (which emphasizes emotion moderation) showed fewer “non-Duchenne” smiles while reliving happy and proud experiences than those who were less identified with Hmong culture.

Cultural differences have also been found in the extent to which emotional facial expressions can be produced voluntarily. Levenson, Ekman, Heider, and Friesen (1992) studied voluntary facial expressions in the Minangkabau of West Sumatra (a matrilineal, Muslim culture that views emotion as interpersonally situated). Levenson et al. used a directed facial action task in which participants were given muscle-by-muscle instructions to construct prototypical emotional facial expressions without mentioning the name of the target emotion. Results revealed that Minangkabau produced lower quality expressions of fear, happiness, and sadness compared to European American controls.

Emotional facial expressions are also sensitive to cultural “display rules,” which can be triggered by cues, including the presence of other members of the culture. In a classic study, Ekman and Friesen (1969; Friesen, 1972) compared emotional facial expressions of American and Japanese students watching a stressful movie. The two groups did not differ in their facial expressions when watching the films. However, when later interviewed about their emotional responses by a Japanese experimenter, Japanese participants exhibited more positive emotion than their American counterparts. The authors concluded that Japanese participants masked their negative emotions in compliance with their culture’s prohibitions against displaying negative emotions in social settings. More recently, Vrana and Rollock (1998) compared African American and European American subjects as they encountered confederates of both races. They found that both groups showed more positive facial expressions during the first few seconds of an encounter with a confederate of their own ethnic background, but subsequently showed greater positive facial expressions with confederates of the other ethnic background. This could reflect an initial spontaneous positive emotional response to encountering a person of one’s own ethnic group, followed by a socially prescribed positive emotional display that might indicate

cooperativeness with an ethnic outgroup member.

Cultural ingroup–outgroup influences on facial expression do not require that the other person be physically present. Roberts and Levenson (2006) found that European American, Chinese American, Mexican American, and African American participants did not differ overall in the amount of emotional facial behavior they displayed when watching emotion-eliciting film clips. However, when ethnic match between the participants and the characters in the films was considered, Chinese American and African American participants displayed more facial expressions of amusement while watching amusing films featuring their own ethnic group than those featuring the other ethnic groups. Vanman, Paul, Ito, and Miller (1997) found that European American college students showed more facial muscle activity consistent with positive emotion when they imagined working with other European Americans than with African Americans. Finally, Vrana and Rollock (2002) found that African American and European American subjects showed more emotional facial responses when imagining interaction with an African American compared to a European American.

Summary

For the “basic” emotions, we are aware of no convincing demonstration of consistent cultural differences in the particular assembly of facial muscles contracted when a given emotion is elicited. This biologically based part of the emotion system appears to be universal. Of course, subtle differences between cultures in the appearance changes that accompany these contractions are quite possible, reflecting differences in facial morphology. Cultural differences are found, however, in the amount and type of emotional expressions that occur in response to emotion elicitors. These differences often reflect cultural norms concerning emotional expression, especially in those individuals most strongly identified with that culture. In addition, the presence of a member of a culture (in person, imagined, or depicted) can result in modulation of emotional expression in culturally consistent ways. Thus, the existing research clearly indicates that the production of emotional facial behavior is influenced by both biology and culture.

Peripheral Physiology

Peripheral nervous system activity, most notably in the autonomic nervous system, plays an important role in many emotion theories, contributing to the subjective experience of emotion, alerting the organism to significant encounters, and preparing the body for action (Levenson, 2003). As with emotional facial expression, there are several fundamental issues about the influence of culture on what is basically a biological system. First, there is the question of cultural differences in the mapping of particular features of the autonomic response onto particular emotions (e.g., are there cultures in which people's blood pressures fall and their faces blanch when they become angry?). Second, there is the question of whether cultures differ in terms of the intensity of the autonomic response overall and/or of the separate organ systems (e.g., do cultures differ in the ratio of cardiac to electrodermal activation in anger?). Despite the fundamental importance of these questions, relatively few studies of cultural influences on emotion have directly measured physiological responses during emotion production. Instead, studies have assessed subjective reports of physiological responses (e.g., beliefs about what is happening in the body), cultural differences in resting or baseline physiological levels (i.e., not measured during emotion production), and physiological reactions to stressful situations (in which a specific emotional response is not identified). These kinds of studies are reviewed below. Also important, but not directly relevant to our focus in this section, are studies of the extent to which individuals in cultures somatize emotions (e.g., Heelas, 1986; Shweder, 1993) and emotional distress (e.g., Kleinman, 1977; Pole et al., 2005).

Subjective Reports of Physiological Response

Subjective reports of physiological responses are not proxies for actual physiological measurement. Research on visceral perceptions has shown that our estimates of physiological activity are often not very accurate (Katkin, Blascovich, & Goldband, 1981; Pennebaker, 1982). Nonetheless, visceral perceptions clearly exist, influence the way we talk about our emotions (Lakoff, 1987), and assume an important role in many emotion theories (Damasio, 1998; James, 1884; Levenson, 2003; Schachter & Singer, 1962).

Wallbott and Scherer (1988) surveyed respondents in 27 countries about the physiological experiences (e.g., relaxed muscles, feeling warm) they associated with anger, fear, guilt, joy, sadness and shame. They found that the amount of variance in subjective physiological responses due to the specific emotion was larger than that due to country, concluding that different cultures have similar subjective appraisals of emotion-related physiology. Other studies, however, have identified differences between cultural groups. Scherer, Wallbott, and Summerfield (1986) asked respondents from Northern and Southern Europe to indicate what bodily responses they experienced during specific emotional states (anger, fear, happiness, and sadness). Each emotion was accompanied by distinguishable bodily signs; however, sadness elicited different responses from Northern and Southern Europeans. Scherer, Wallbott, Matsumoto, and Kudoh (1988) repeated the study in a sample of U.S. and Japanese students. They found that U.S. students reported physiological states similar to those reported by European respondents in the earlier study; however, Japanese respondents reported far fewer physiological reactions. Probably the most dramatic findings of cultural variation measured by subjective physiological responses were reported by Hupka, Zbigniew, Jurgen, and Reidl (1996). Students in Mexico, Russia, Poland, Germany, and the United States rated the extent to which they felt anger, fear, jealousy, and envy in specific parts of their bodies (e.g., bones, heart). Findings suggested several cross-cultural similarities (e.g., respondents from all nations reported feeling envy and jealousy in the breath, chest, and heart) and a number of differences (e.g., only respondents from the United States reported feeling envy and jealousy in their eyes, face, stomach, and tears). Given that physiology was not directly measured in this paradigm, the authors interpreted their findings as most likely reflecting cultural stereotypes and emotion metaphors.

Resting or Baseline Physiological Levels

A number of studies have examined cultural differences in physiological states measured in the *absence* of any specific, emotion-eliciting stimuli. Depending on the research tradition, measures obtained in this manner can be described as "tonic" (vs. "phasic"), "trait" (vs.

“state”), or “resting” (vs. “reactive”). Most of these studies have compared African Americans and European Americans, in an attempt to understand the high incidence of essential hypertension (i.e., chronic high blood pressure of unknown etiology) in African Americans (Akinkube, 1985). Findings suggest that African Americans begin life with faster resting heart rates than their European American counterparts (Lee, Rosner, Gould, Lowe, & Kass, 1976; Schachter, Kerr, Wimberly, & Lachin, 1974; Schachter, Lachin, Kerr, Wimberly, & Ratey, 1976) but achieve similar heart rates to European Americans by adolescence (Schachter, Kuller, & Perfetti, 1984; Shekelle, Liu, Raynor, & Miller, 1978; Voors, Webber, & Berenson, 1982) and that this equivalency continues into older age (Persky, Dyer, Stamler, Shekelle, & Schoenberger, 1979). In addition, compared to European Americans, African Americans have been found to have lower resting skin conductance levels (L. C. Johnson & Corah, 1963; L. C. Johnson & Landon, 1965; Juniper & Dykman, 1967; Korol, Bergfield, & McLaughlin, 1975; Lieblich, Kugelmass, & Ben-Shakhar, 1973; Morell et al., 1988) and higher resting blood pressure levels (Levinson et al., 1985; Morell et al., 1988; Roberts & Rowlands, 1981). The reasons for these differences are not fully understood. For example, differences in skin conductance have been attributed to darker skin pigmentation and differences in the number of active sweat glands (Boucsein, 1992). However, these assertions have not always been supported empirically (L. C. Johnson & Landon, 1965; Korol et al., 1975).

Ethnocultural differences in resting physiological levels are not readily interpreted in terms of emotions but may reflect more enduring factors such as mood, styles of emotion regulation, and sensitivity to contextual cues. Brownley, Light, and Anderson (1996) found that high hostility levels were associated with higher blood pressure in European Americans, but lower blood pressure in African Americans. E. H. Johnson (1989) found that African American adolescents suppressed anger more frequently and had higher blood pressure than their European American counterparts. Lazarus, Tomita, Opton, and Kodoma (1966) found that Japanese participants showed higher skin conductance levels than U.S. participants, despite reporting similar levels of distress. Closer analysis of the

skin conductance data revealed that the higher skin conductance levels in the Japanese participants occurred throughout the experiment, and not just in response to the film stimuli, arguably reflecting their greater concern about the experimental situation.

Stressful Situations

In these studies, cultural groups are exposed to challenging situations. The situations are generically stressful; thus, it is difficult to know exactly which emotion(s) are being produced. Because emotion is not the primary focus of these studies, researchers typically do not query subjects about their emotional experience or measure emotional expressive behavior. As in the previous section on resting levels, the majority of these studies have compared African Americans and European Americans. Anderson, Lane, Muranaka, Williams, and Houseworth (1988) found African Americans to have greater increases in blood pressure and forearm vascular resistance, but no differences in heart rate reactivity in response to a cold stressor (ice pack applied to forehead) compared to European Americans. Alpert et al. (1981) found African Americans to have higher blood pressure reactivity than European Americans to an exercise stressor, but found no ethnic differences in heart rate reactivity. Hohn et al. (1983) found that among participants with a family history of hypertension, African American children had larger blood pressure responses than European American children to an exercise stressor. Murphy, Alpert, Moes, and Somes (1986) found that African American children had greater blood pressure reactivity than European American children to a video game. Finally, Jackson, Treiber, Turner, Davis, and Strong (1999) found that African Americans showed greater reactivity in systolic and diastolic blood pressure to a range of physical and psychological stressors, but European Americans showed greater reactivity in heart rate. Consistent with these findings, this literature is often summarized as indicating that African Americans have greater cardiovascular reactivity to stress than do European Americans. However, it is important to note the sizable number of contrary results (e.g., Anderson et al., 1988; Anderson, Lane, Taguchi, & Williams, 1989; Delehanty, Dimsdale, & Mills, 1991; Falkner & Kushner, 1989; Morell et al., 1988; Saab et al., 1997).

Emotion Production

Studies in which the influence of culture is assessed by physiological responses measured directly during emotion production are critical for understanding the interplay between culture and biology. The simplest emotional stimulus for which cultural differences have been studied in this way is the acoustic startle. Although the initial response to the startle (i.e., in approximately the first 500 milliseconds) is arguably more a reflexive defensive reaction than an emotion, it is often followed by a rich emotional response (Ekman, Friesen, & Simons, 1985). Korol et al. (1975) found that African Americans had smaller skin conductance responses to an acoustical startle than did European Americans, a finding they interpreted as related to the lower resting skin conductance levels commonly found among individuals with darker skin. Soto et al. (2005) found no physiological differences in responses to an acoustical startle between Mexican Americans and Chinese Americans. When King and Levenson (2004) expanded this study to include African Americans and European Americans, they also found no ethnic group differences in physiological response.

Studies of prejudice (see Guglielmi, 1999, for a review) often examine the emotional reaction of a person from one race to encountering someone from another race. Rankin and Campbell (1955) found that European American males had larger skin conductance responses when interacting with African American than did their European American confederates. Vrana and Rollock (1998) found that African American and European American males had larger increases in heart rate when encountering African American confederates compared to European American confederates.

Social interaction between partners in committed, intimate relationships is an extremely rich source of emotion (Gottman & Levenson, 1986). Tsai and Levenson (1997) examined physiological responses of Chinese American and European American couples in committed dating relationships as they engaged in a 15-minute discussion of an area of relationship conflict. Levels of physiological arousal provoked by the conflict did not differ between the two ethnic groups.

Only a handful of studies of cultural influences in emotion have directly measured physiology in response to well-defined stimuli de-

signed to elicit specific emotions. All of the studies on emotional facial expressions from our laboratory and from the Tsai laboratory, reviewed in an earlier section, also included an extensive set of autonomic measures (typically including measures of cardiovascular, electrodermal, respiratory, and somatic activity), and most found no significant cultural differences in measures of peripheral physiological response. Levenson et al. (1992) found that physiological responses to emotional facial configurations using the directed facial action task were the same in Minangkabau participants living in West Sumatra and in European American controls. Tsai et al. (2000) found no differences in physiological response to sad and amusing films in Chinese American and European American participants. Roberts and Levenson (2006) found no overall differences in the physiological responses of African American, Chinese American, European American, and Mexican American participants in response to amusing, disgusting, and sad films. Tsai et al. (2003) found no ethnic differences in physiological response to imagined emotional scenarios in Scandinavian Americans and Irish Americans.

There are two exceptions to this general trend of no cultural differences. Tsai et al. (2002) found that Hmong Americans had smaller skin conductance responses than their European American counterparts while reliving a "love" memory. Vrana and Rollock (2002) found that African Americans had larger blood pressure responses than European Americans when imagining emotional scenarios.

Summary

The literature on cultural influences on peripheral physiological response suggests that culture may have an influence on subjective reports of physiological response, resting physiological levels, and physiological responses to generalized stress. However, in the realm of directly measured physiological response to well-defined emotional stimuli, the impact of culture appears to be relatively minimal. Nonetheless, within this scant literature, with contributions by only a few laboratories, caveats abound. Still, it does seem to be the case that for the two biological systems being considered in this review, cultural influence on peripheral physiological response is less pro-

found than that on facial expression. This notion that cultural “penetrance” or influence varies for different aspects of emotion plays a central role in the theoretical formulation presented in the next section.

TOWARD AN EMPIRICALLY INFORMED BIOCULTURAL THEORY

One failing of most theories of emotion that have considered cultural influences is that they have treated emotion as a monolith. Thus, culture is viewed as having an effect on emotion in its entirety rather than as having more variable levels of influence depending on features of the emotion, context, and person. Viewed in this more differentiated way, cultural influences may vary for aspects of emotion (e.g., subjective experience, language, expressive behavior, peripheral physiology), type of emotion (e.g., negative emotion, positive emotion, self-conscious emotion), context (e.g., presence of culturally salient cues), and the individual (e.g., extent of identification with cultural traditions). As the body of cross-cultural and cross-ethnic empirical research on emotion has increased, it has become increasingly clear to us that the impact of culture on emotion is anything but uniform.

Components of Emotion: Differential Susceptibility to Cultural Influence

Although this chapter focuses on the impact of culture on two biological systems, facial expression and peripheral physiology, a number of studies from our laboratory and others have examined self-reported subjective emotional experience as well. Upon examination of this work in its entirety, a clear pattern emerges: (1) Self-reported subjective emotional experience is *highly* susceptible to cultural influence—often mirroring ethnographic descriptions of cultural values and mores; (2) emotional expressive behavior is *somewhat* susceptible to cultural influence; and (3) autonomic nervous system response is *minimally* susceptible to cultural influence.

The cultural malleability of self-reported emotional experience is dramatically demonstrated in our work with the directed facial action task conducted in West Sumatra with the Minangkabau (Levenson et al., 1992). When Minangkabau and European American con-

trols produced emotional facial configurations, they activated the same patterns of autonomic nervous system activity. However, the Minangkabau were *much* less likely than European Americans to report feeling the associated emotion. Even after taking into account cultural differences in the ability to produce the facial configurations, this difference in self-reported subjective experience remained. Moreover, our careful translation–backtranslation work and testing of how emotion terms were used with other emotion-eliciting tasks (not reported in the published work) indicated that translation inequivalencies were not responsible for this finding. Thus, we found members of two different cultures could produce the same emotional configurations on their faces and have the same attendant autonomic nervous system activity but report very different subjective emotional states. Our speculation as to the basis of this difference was that emotion is viewed as more of an internal state in European American culture, and as more of an interpersonal condition in Minangkabau culture. Thus, a situation in which facial and physiological aspects were activated (along with the attendant somatic and visceral sensations) would be sufficient for labeling the state as “emotion” for European Americans, but not for Minangkabau, for whom it lacked the appropriate interpersonal grounding.

The previously described research by Soto et al. (2005) also illustrates this pattern using a more “conventional” emotional elicitor. In this study, Chinese Americans reported experiencing significantly less emotion than did Mexican Americans in response to an aversive acoustical startle stimulus. This is consistent with ethnographic descriptions of Chinese culture as a culture of emotional moderation and of Mexican culture as a culture of emotional expression. However, in the realm of emotional behavior, evidence for greater emotional expression in Mexican Americans than in Chinese Americans was only found when participants who most strongly identified with their culture of origin were compared. Physiological differences among the groups were minimal. Why would this differential susceptibility to cultural influence exist? We believe it primarily reflects the extent to which these different aspects of the emotional response are amenable to voluntary control and, to some extent, the social visibility of those components.

Self-Reported Emotional Experience

We do not view the ways we label our emotional states as being predetermined by biological “hardwiring,” but rather as quite malleable, reflecting factors such as situational cues, visceral sensations, cultural values and mores, and “feeling rules” (Hochschild, 1979). In most situations we are able to exert a great deal of voluntary control over what we *say* we are feeling. These emotion labels are highly socially visible events; thus, there is a strong incentive to modulate this aspect of our emotional response in culturally sanctioned ways. Arguably, when emotions are extremely intense, or when we are dealing with immediate utterances rather than retrospective reports, this modulation becomes more difficult.

Emotional Facial Expressions

We believe that the set of facial muscles that contracts for particular “basic” emotions such as anger, disgust, fear, happiness, sadness, and surprise is determined by hardwired, involuntary neural circuitry. However, the innervation of the facial muscles is such that voluntary pathways can, under some conditions, alter and override these expressions (Rinn, 1984). For example, in a series of emotional suppression studies, we found that participants can dramatically decrease and increase the amount of facial behavior produced by emotion-eliciting films and acoustic startle stimuli (Gross & Levenson, 1993; Hagemann, Levenson, & Gross, 2006; Kunzmann, Kupperbusch, & Levenson, 2005). Thus, in theory, people should be able to comply with cultural “display rules.” However, the empirical evidence suggests that modulation of facial displays in culturally proscribed ways is much *less* likely to be observed than modulation of self-reported emotional experience. It is important to note that despite the huge theoretical impact the display rule notion has had on the field of emotion research, empirical tests have been quite limited. The original research on display rules (Friesen, 1972) did not find cultural difference when participants viewed films, only when they discussed them afterwards. In more contemporary studies with bicultural participants, cultural differences have often been limited to those participants with the strongest identification with their culture of origin (Soto et al., 2005; Tsai et al.,

2002). Facial expressions are clearly socially visible; nonetheless, the importance of controlling them may be lessened by several factors. For example, although people have proved to be quite good at identifying the emotional meaning of static photographs of high-intensity expressions, they may be less accurate at identifying the emotional meaning of low-intensity and brief facial expressions (Ambadar, Schooler, & Cohn, 2005). In addition, cultural conventions may place limits on attending to and labeling the facial expressions of others (e.g., Goffman, 1971). These inaccuracies, coupled with culturally proscribed neglect, may make it relatively “safer” to allow true feelings to show on the face.

Autonomic Nervous System Response

The autonomic nervous system is designed to function automatically and in general is not subject to direct voluntary control (Levenson, 1979). Although a great deal of autonomic activity is socially invisible (e.g., regulation of core temperature), the autonomic nervous system is also responsible for producing a number of highly visible, emotionally relevant appearance changes (e.g., blushing, blanching; for a comprehensive listing, see Levenson, 2003). Thus, there clearly are good reasons to try to modulate autonomic activity to conform to social norms. Nature, however, has wisely *not* provided us with the tools to override easily the essential biological functions the autonomic nervous system serves. Consistent with this, in our own work, we have found few physiological differences between cultural groups relative to those found in emotional facial expression and self-reported emotional experience. Several caveats, however, must accompany this observation. First, interpretations of failure to find differences between cultural groups must be tempered by considerations of sample size/power and the impossibility of proving null hypotheses. Second, when cultural groups appraise the eliciting situation in ways that result in different emotional states, we would expect physiological differences consistent with those states to occur (e.g., when an epithet caused Southerners to feel insulted but had little effect on Northerners, Southerners showed a larger endocrine response; Cohen, Nisbett, Bowdle, & Schwarz, 1996). These caveats notwithstanding, the lack of consistent findings of cultural differences in autonomic activity is impressive.

A Revised Biocultural Model of Emotion

The growing body of empirical data on cultural influences on emotion reviewed in this chapter suggests several revisions to our original biocultural model of emotion (Levenson, 2003). In the revised model, presented in Figure 32.1, a core system (inside the large rectangle) continuously scans incoming information in search of patterns that match one of a limited set of configurations that match prototypical challenges and opportunities (e.g., loss of support, presence of attachment object). When a match occurs, a hardwired organized set of response tendencies (i.e., an emotion) is activated. This set of response tendencies has been selected by evolution for having the highest probability of dealing successfully with that kind of situation most of the time. For simplicity, in this version, we have omitted some of the additional response systems that are recruited (e.g., perception, attention, purposeful behavior, vocalization, gross motor activity, gating of higher mental processes—see Levenson, 1999, for a more complete set). The different patterns of activation of these systems, especially the visceral and somatic sensations and proprioceptive feedback, contribute to the subjective

experience of different emotions. All of this occurs automatically, without conscious intervention. As such, it does not allow for a great deal of learned cultural influence.

In humans, the core system is encapsulated by a control system (outside the large rectangle) that influences both the input to and output from the core system. On the input side, an appraisal system can alter the extent to which an event matches a prototype, thus influencing whether an emotion is elicited by a particular event, and if so, which emotion. For example, a sudden loss of support experienced during a roller-coaster ride may be appraised in a way that makes it less life threatening; thus, it is less likely to produce fear and more likely to produce amusement or excitement. On the output side, another part of the control system alters the likelihood that a response tendency activated in the core will lead to its usual, observable response (e.g., whether a tendency to show a facial expression of disgust when viewing a decaying body results in an observable disgust expression or a neutral face; whether a particular configuration of visceral sensations is labeled as disgust or not). It should be noted that the control system can both increase and decrease the likelihood of a given event resulting

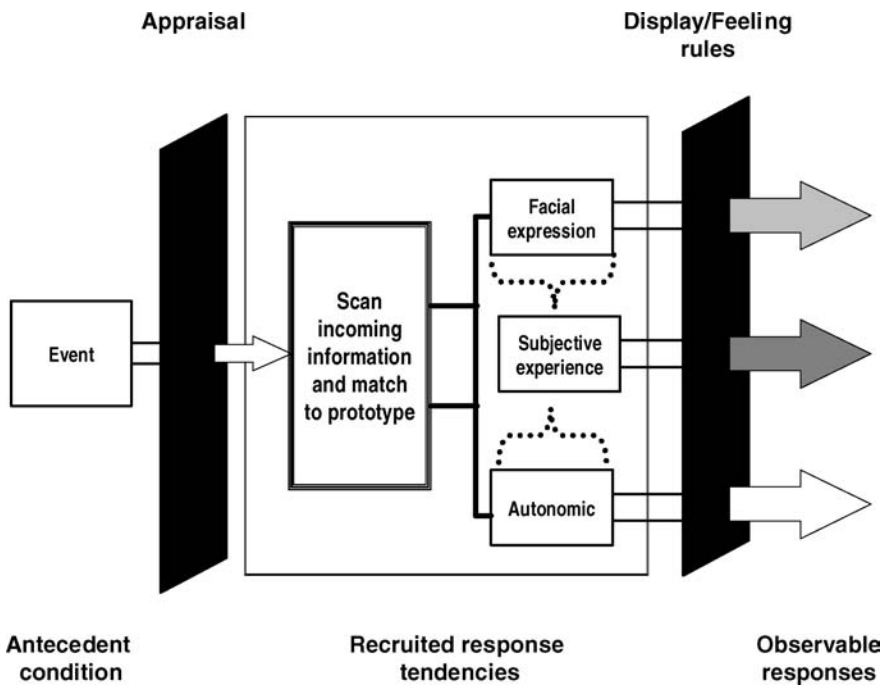

FIGURE 32.1. Revised biocultural model of emotion.

in an emotion and its typical, associated responses. Cultural influences on emotion occur in both aspects of the control system, in the ways that the world is appraised (e.g., what is dangerous, what is safe) and in the extent to which emotional response tendencies are expressed (e.g., conventions and values concerning emotional expression and experience, such as display rules and feeling rules).

In this revised model (Figure 32.1) the differential susceptibility of emotion response systems to cultural influence is depicted in the shading of the observable responses—with darker arrows indicating greater cultural influence. Thus, autonomic response tendencies pass through the control system relatively unin-

fluenced, facial expression tendencies are somewhat influenced, and self-reports of subjective emotional experience are highly susceptible to cultural conventions.

Modulating Cultural Influence

We believe that the extent of influence culture has on the various components of emotion is not fixed, but rather is modulated dynamically by a number of features of the emotion, context, and person. We present our ideas about modulators in Table 32.1 below along with empirical support where available. Should these hypotheses about the modulating influences of culture prove to be correct, they will indicate

TABLE 32.1. Moderators of Cultural Influence on Emotion

Modulator	Greater cultural influence on emotion associated with	Rationale
Acculturation/stage of ethnic identity	Stronger immersion in and identification with cultural beliefs and mores about emotion	Familiarity with cultural norms and reinforcement history of rewards for conforming to these norms increases likelihood of future conformity (Soto et al., 2005; Tsai et al., 2002).
Intensity	Less intense emotion	Strong emotion “floods” system, making voluntary control more difficult.
Timing	More gradual onset of emotion	Rapid onset cuts off opportunity to reappraise situations and to “brace” against the natural expression of the emotion.
Match to prototypical elicitor	Antecedent condition more distal from a prototypical elicitor	Species-relevant prototypical elicitors (e.g., loss of support as prototypical fear elicitor in humans) have strong evolved hardwired circuitry that is extremely difficult to modulate. Antecedents that diverge from prototypes produce weaker response tendencies that are easier to override and alter.
Class of emotion	Emotions that are more self-referential than survival-oriented	Self-referential emotions (e.g., pride, shame, guilt) are more culturally constructed (Kitayama, Markus, & Matsumoto, 1995), more directly embody cultural norms, and have less strongly evolved hardwired circuitry than survival-oriented negative emotions (e.g., fear, anger). Positive emotions likely fall somewhere in between. Emotions, such as disgust, that have not only hardwired origins but also “moral” extensions (Rozin, Lowery, Imada, & Haidt, 1999) could provide particularly interesting tests.
Social context	Presence (real or imagined) of other members of ethnic group or cultural cues	Ethnic ingroup members and other culturally relevant symbols (language, food, etc.) can cue cultural norms, making them more salient and more likely to influence emotion (Kitayama, Markus, Matsumoto, & Norasakkunkit, 1997; N. A. Roberts & Levenson, in press; Vanman, Paul, Ito, & Miller, 1997; Vrana & Rollock, 2002).

important issues for researchers to consider and control for when attempting to evaluate, compare, and aggregate findings concerning cultural influences on emotion.

FUTURE DIRECTIONS

Studying the influences that culture has on actual emotion production provides a rich and fertile direction for future research. Such research arguably provides the third essential leg of a modern empirical science of culture and emotion consisting of emotional ethnography (critical for hypothesis generation and interpretation of results); studies of emotion perception, understanding, and values (critical for understanding the ways that culture influences our thinking about emotion); and studies of emotion production (critical for discovering the influences of culture on different emotion systems as emotions unfold over time). Studies of culture and emotion production lend themselves readily to experimental designs in which cultural variables are carefully manipulated (e.g., presence of culture-salient cues) and their influence on emotional responding precisely measured. Because cultural influences on emotion production likely accumulate over time, longitudinal designs could be particularly useful in documenting how people become culturally competent in the emotional realm. Greater use of experimental and longitudinal designs in research on culture and emotion production could be quite helpful in moving this highly important area of inquiry more prominently into the scientific mainstream.

In the previous section, we suggested a number of possible modulators of the influence of culture on emotional responding, and provided some hypotheses about the nature of these modulating influences. These hypotheses are outgrowths of our notions about the nature of emotion and culture, and about their interactions. Of course, other theoretical starting points could lead to quite different predictions. What is important is that the portfolio of research on the influence of culture on emotion, which has traditionally had a strong investment in using descriptive and qualitative methods, and in measuring emotional judgments, should also have a strong investment in using experimental and quasi-experimental methods

to test falsifiable hypotheses and to explore causal, mediating, and moderating influences on actual emotion production.

CONCLUSION

In this chapter we have reviewed the literature that has considered cultural influences on two of the primary biological systems in emotion—facial expression and peripheral physiological response. Many of these studies include self-report measures of emotional experience, and these data have also been considered. Although there have been a large number of studies of cultural influences on the ability to *recognize* the emotions being expressed by others, we have given primary consideration to studies of emotion *production* in which these biological systems have been directly measured during actual emotions. Based on this body of research, we conclude that cultural influences in emotion vary depending on which aspect of emotion is being considered, with the strongest influence on self-reported emotional experience, somewhat weaker influence on emotional facial expression, and relatively minimal influence on autonomic nervous system response. These findings led us to present a revision of our earlier biocultural model of emotion (Levenson, 2003) that now explicitly reflects varying cultural influence on different aspects of emotion. We have also articulated some testable, but admittedly speculative, hypotheses about characteristics of emotion, context, and person that modulate the extent of cultural influence. These modulatory influences extend our general conclusion that the influence of culture on emotion is neither monotonic nor constant, but rather is nuanced and variable.

We recognize that some of these conclusions are based on a relatively small number of studies that met our criteria for directly measuring biological response during actual emotional episodes. We hope that additional studies of this nature will enable us to test and refine these notions. It is important that studies of cultural influences on the biology of emotion be held to the same high standards of methodology necessary for any study of cultural influence. For example, sample selection criteria are particularly important when working with “domestic” samples to ensure that they are truly represen-

tative of the cultural traditions of interest. Bicultural college students are often quite capable of “code-switching” (i.e., shifting between their culture of origin and their adopted “mainstream” culture); thus, it is important to be sensitive to the extent that the laboratory environment is providing cues as to what behavior is “appropriate” (e.g., the ethnic match between experimenters and participants). Studies assessing multiple aspects of emotion present special analytical challenges in attempts to apportion cultural influences among the measured systems (e.g., is the found cultural influence on facial expression more or less than would be expected given the found cultural influence on peripheral physiology?). Moreover, researchers need to consider factors that could modulate the impact of culture on emotion (e.g., intensity of stimuli, type of emotion, acculturation level of participants) when attempting to aggregate findings across different studies.

Emotion provides an ideal stage for studying the interplay of culture and biology, nature and nurture, and contexts and individuals. We are still at a relatively early stage in the study of cultural influences on the biology of emotion. As this research area continues to mature, we expect the theoretical and practical yield for understanding culture, emotion, and their interaction to be considerable.

CHAPTER 33

Culture and Psychopathology

Foundations, Issues, and Directions

ANTHONY J. MARSELLA
ANN MARIE YAMADA

Shall we write about the things
not to be spoken of?
Shall we divulge the things
not to be divulged?
Shall we pronounce the things
not to be pronounced?
—JULIAN THE APOSTATE (332–363 C.E.)
Hymn to the Mother of the Gods

After decades of relative neglect and marginalization within psychiatry, the study of the relationship between culture and psychopathology has emerged as topic of considerable interest and influence. In 1994, under pressure from ethnic minority and international psychiatric professionals, the American Psychiatric Association included new sections in the fourth edition of *Diagnostic and Statistical Manual of*

Mental Disorders (DSM-IV) under the titles “Glossary of Culture-Bound Syndromes” and “Outline for the Cultural Formulation of Case.” Though these sections appeared at the very ends of the book (pp. 843–849), they nevertheless signaled a new era in psychiatry, in which cultural factors would now be given increased attention in our understanding of the etiology, expression, assessment, diagnosis, and

treatment of psychopathology. Of particular note is the warning statement inserted at the beginning of DSM-IV and DSM-IV-TR (American Psychiatric Association, 1994, p. xxiv; 2000, p. xxxiv). This statement, perhaps more than any other in psychiatry, encourages clinicians and researchers to be sensitive to cultural variations or risk serious mistakes: "A clinician who is unfamiliar with the nuances of an individual's cultural frame of reference may incorrectly judge as psychopathology those normal variations in behavior, belief, or experience that are particular to the individual's culture."

The fact that this increased responsiveness to cultural variables occurred in a time when biological and other reductionistic views of psychopathology dominated professional training, clinical applications, and research adds to the significance of what occurred and emphasizes the important influence of "political" forces in our work. The mental health professions would now be asked to consider "cultural" variables in their case construction, their training curricula, and their research efforts. Even with this, a gap remains between the fields of psychiatry and psychology. This chapter provides an overview of the study of culture and psychopathology, with special emphasis on its historical development, basic assumptions, theoretical and empirical findings, and related issues.

FORCES FOR CHANGE

The forces that led to these changes are numerous and deserve to be mentioned, because they reveal how our scientific and professional knowledge and practice are often determined not by "science" but by the particular people, theoretical orientations, and ideologies that hold the power and that come to dominate a field (e.g., biological reductionism). Clearly, although there was considerable evidence of cultural and ethnic bias and abuses in psychiatric practice, cultural considerations were ignored, and pressures for change ultimately required a "political" response in which ethnic minority and international voices called for significant changes in DSM-IV (e.g., Chakraborty, 1991; Mezzich, Kleinman, Fabrega, & Parron, 1996; Rogler, 1996).

The changes were facilitated by a number of

events and forces that converged between 1980 and the present:

1. Increasing numbers of ethnic minority and international psychiatrists and social scientists gave increased power to their voices. Sometimes motivated by anger, resentment, and the problem of irrelevance, these voices raised questions about the universal applicability of Western concepts of illness and health.
2. Research was seen as inadequate, because it was often limited to Western samples; when research on ethnic/minority and non-Western patients did occur, it was conducted from a Western viewpoint and knowledge base.
3. Increases occurred in political and social awareness of the pathological consequences of racism, sexism, imperialism, colonialism, and other "isms" that produce powerlessness, marginalization, and underprivileging among sizable population sectors.
4. There emerged a new awareness of the multiple and interactive determinants of psychopathology (e.g., biological, psychological, cultural, sociological, spiritual, environmental).
5. Proliferation of scientific and professional communication networks and outlets promoted interest in the topic across the world through professional societies (e.g., International Association of Cross-Cultural Psychology, World Federation for Mental Health, World Psychiatric Association), journals (e.g., *Transcultural Psychiatry*, *Culture, Medicine and Psychiatry*, *Hispanic Journal of Behavioral Sciences*, *Cultural Diversity and Ethnic Minority Psychology*).
6. Development of cooperative international studies of psychiatric disorders by the World Health Organization (e.g., International Pilot Study of Schizophrenia; Determinants of Outcomes of Severe Mental Disorders) not only revealed cultural variations in disorder but also trained a growing number of non-Western psychiatric professionals capable and willing to critique contemporary psychiatry. Within psychology, the pioneering work of Juris Draguns (1973, 1980, 1990; Draguns & Tanaka-Matsumo, 2003) provided systematic coverage of major issues, conceptual models, and therapeutic considerations.

HISTORICAL CONSIDERATIONS

Concern for the sociocultural determinants of psychopathology can be traced to the 18th and 19th centuries, when philosophers (e.g., Jean Jacques Rousseau, Karl Marx), and physicians (e.g., Freud, Kraepelin) raised questions about the contributions of culture to the etiology, expression, and treatment of mental disorders. Emil Kraepelin (1904), the father of our contemporary diagnostic system, suggested that cultural variables need to be considered in understanding mental disorder, and he suggested that a new specialty area be created—*Vergleichende Psychiatrie*, or comparative psychiatry. Kraepelin wrote:

The characteristics of a people should find expression in the frequency as well as the shaping of the manifestations of mental illness in general; so that comparative psychiatry shall make it possible to gain valuable insights into the psyche of nations and shall in turn also be able to contribute to the understanding of pathological psychic processes. (1904, p. 434)

In the years that followed, a score of terms emerged as culture and psychopathology were studied in different disciplines: transcultural psychiatry, cross-cultural psychiatry, comparative psychiatry, ethnopsychiatry, cultural psychiatry, psychiatric anthropology, and even the “new” transcultural psychiatry. A detailed review of these terms and of the history of the field from its beginnings to the 1980s can be found in Marsella (1993).

RESISTANCE TO WESTERN VIEWS

Initially, many of the critiques were commentaries designed to raise consciousness about the ethnocentric biases inherent in Western psychiatry. For example, Chakraborty (1991), an Asian Indian psychiatrist, wrote:

Even where studies were sensitive, and the aim was to show relative differences caused by culture, the ideas and tools were still derived from a circumscribed area of European thought. This difficulty still continues and, despite modifications, mainstream psychiatry remains rooted in Kraepelin’s classic 19th century classification, the essence of which is the description of the two major “mental diseases” seen in mental hospitals in

his time—schizophrenia and manic depression. Research is constrained by this view of psychiatry. A central pattern of (Western) disorders is identified and taken as the standard by which other (local) patterns are seen as minor variations. Such a construct implies some inadequacy on the part of those patients who fail to reach “standard.” Though few people would agree with such statements, there is evidence of biased, value-based, and often racist undercurrents in psychiatry. . . . Psychiatrists in the developing world . . . have accepted a diagnostic framework developed by Western medicine, but which does not seem to take into account the diversity of behavioral patterns they encounter. (p. 1204)

Kirmayer (1998), Editor-in-Chief of the journal *Transcultural Psychiatry*, captured the dilemma facing those supporting the “new” transcultural psychiatry and those holding traditional psychiatric medical perspectives, when he wrote:

While cultural psychiatry aims to understand problems in context, diagnosis is essentializing: referring to decontextualized entities whose characteristics can be studied independently of the particulars of a person’s life and social circumstances. The entities of the DSM implicitly situate human problems within the brain or the psychology of the individual, while many human problems brought to psychiatrists are located in patterns of interaction in families, communities, or wider social spheres. Ultimately, whatever the extent to which we can universalize the categories of the DSM by choosing suitable level of abstraction, diagnosis remains a social practice that must be studied, critiqued, and clarified by cultural analysis. (1998, p. 342)

THE CLINICAL AND RESEARCH LITERATURE

However, critical commentaries soon yielded to a widespread, implicit understanding that cultural factors are critical in shaping the onset, expression, course, and outcome of psychopathology. It was simply a case of a gathering mass of evidence combined with a new consciousness of the power of culture in shaping both normal and abnormal behavior. No single event nor publication turned the tide in favor of increased attention to cultural variables. However, certain publications are considered by many to have had a profound influence on the field. For example, within psychology, the

publication of the *Handbook of Cross-Cultural Psychology: Vol. VI. Psychopathology* (Triandis & Draguns, 1981) did much to articulate the relationship between culture and various forms of psychopathology, such as depression, schizophrenia, and disorders of everyday life. In anthropology, a series of publications from the University of Hawaii/National Institute of Mental Health (NIMH) Culture and Mental Health Program (e.g., Caudill & Lin, 1969; Lebra, 1972) served to raise clinical and scientific consciousness about cultural variations in psychopathology. In psychiatry the pioneering work by Alexander Leighton and his colleagues (1959; Leighton et al., 1963) laid the sociocultural foundations of psychopathology. By the 1970s and 1980s, publications by Kleinman (1980) and Marsella and White (1982; Marsella & Higginbotham, 1984) offered theoretical foundations for understanding the role of sociocultural factors in psychopathology. In 1992, the American Psychological Association (1992) published guidelines for providers of psychological services to ethnic, linguistic, and culturally diverse populations in which the need for familiarity with the patient's background was advocated.

Of particular importance in strengthening interest in culture and psychopathology was the volume *Culture and Depression* (Kleinman & Good, 1985), which applied the ideas of the new "transcultural psychiatry" to the topic of depression. This volume emphasized the importance of "context," asserting that depressive experience and disorder could be understood apart from the cultural context in which it was embedded. Indeed, it was noted that depressive experience and disorder might not have the same meaning or implications across cultural boundaries, or the same expressions or etiologies. The widespread impact of this volume was provided by a collection of substantive chapters written by experienced clinicians and academics.

Within the last decade, a number of books have offered overviews of the culture and psychopathology field (e.g., Castillo, 1996; Cuellar & Paniagua, 2000; Mezzich & Fabrega, 2001), and topics such diagnosis/classification (e.g., Mezzich et al., 1996; Paniagua, 2001) and specific disorders such as posttraumatic stress disorder (PTSD; Marsella, Friedman, Gerrity, & Scurfield, 1996). It is notable that a topical specialization in ethnocultural variations in responsiveness to medications has

also emerged, under the rubric of "ethnopsychopharmacology," in the work of Keh Ming Lin (e.g., Lin, Smith, & Ortiz, 2001). A number of books have also appeared that address cultural variations in psychopathology among specific ethnic and racial populations including minorities (e.g., Bernal, Trimble, Burlew, & Leong, 2003; Littlewood & Lipsedge, 1997), Native Americans (O'Neil, 1998), Chinese (e.g., Lin, Tseng, & Yeh, 1999; Phoon & Macindoe, 2003), and Hispanics/Latinos (e.g., Becerra, Karno, & Escobar, 1982; Carrillo & Lopez, 2001; Telles & Karno, 1994).

Yet another important event in shaping the study of culture and psychopathology came via the U.S. Department of Health and Human Services (DHHS; 2001) in its published report *Mental Health: Culture, Race, and Ethnicity*. In this report, the DHHS reached specific conclusions about the role of culture and forcefully stated, "Culture counts!" The report detailed disparities in the provision of psychiatric services to racial/ethnic minorities in the United States and called for renewed efforts to address these problems:

The main message of this supplement is that "culture counts." The cultures that patients come from shape their mental health and affect the types of mental health services they use. Likewise, the cultures of clinician and the service system affect diagnosis, treatment, and the organization and financing of services. Cultural and social influences are not the only influences on mental health and service delivery, but they have been historically underestimated—and they do count. Cultural differences must be accounted for to ensure that minorities, like all Americans, receive mental health care tailored to their needs. (p. 14)

In brief, after years of limited attention, the study of culture and psychopathology has now assumed a prominent position within the professional and scientific efforts of psychiatry and the social sciences. The result is that our understanding of psychopathology will never be the same!

THE CONCEPT OF CULTURE AND ITS IMPORTANCE FOR PSYCHOPATHOLOGY

Defining Culture

If we are to understand the relationship of culture to psychopathology, it is critical that we

first understand the concept of culture. Definitions of culture are numerous and varied. More than a half-century ago, Kroeber and Kluckhohn (1952) had already summarized more than 125 definitions. For our purposes, we use the following definition:

Culture is shared, learned behavior and meanings that are socially transferred in various life-activity settings. Cultures can be (1) *transitory* (i.e., situational, for even a few minutes) or (2) *enduring* (e.g., ethnocultural lifestyles), and in all instances are (3) *dynamic* (i.e., constantly subject to change and modification). Cultures are represented (4) *internally* (i.e., values, beliefs, attitudes, images, symbols, orientations, epistemologies, consciousness levels, perceptions, expectations, personhood) and (5) *externally* (i.e., artifacts, roles, institutions, social structures). Cultures (6) *shape and construct our realities* (i.e., they contribute to our worldviews, perceptions, orientations) and, with this, frame many critical concepts (e.g., normality-abnormality, morality, aesthetics).

The virtue of this definition is that it captures the dynamic complexity of cultural experience and the fact that culture, while represented externally in artifacts, roles, and institutions, also is represented internally in the human psyche, in many forms that ultimately shape both normal and abnormal behavior (e.g., values, beliefs, epistemologies). The influence of cultural factors on psychopathology is now well accepted. That this should be the case is not surprising. The rates, etiology, diagnosis, and expression or manifestation of psychopathology are all culturally constructed and contextualized. Variations in stresses, coping resources, definitions of health and illness, and a score of cultural variables, such as language, dietary preferences, morality codes, and definitions of personhood, all converge to shape psychopathology.

Our views of reality are culturally constructed (Marsella, 1999)! Our worldviews—our cultural templates for negotiating reality—emerge from our inborn human effort after meaning, an effort that reflexively provokes us to describe, understand, predict, and control the world about us through the ordering of stimuli into complex belief and meaning systems that can guide behavior. The brain not only responds to stimuli, it also organizes, connects, and symbolizes them, and, in this process, generates patterns of explicit and implicit meanings and purposes that promote survival,

growth, and development. This process occurs through socialization and often leads us to accept the idea that our “constructed” realities are in fact realities. The “relativity” of the process and product is ignored in favor of the “certainty” provided by the assumption that our way of life is correct, righteous, and indisputable (e.g., ethnocentricity).

Sometimes, an entire cultural milieu may be pathogenic. For example, Edgerton (1992) coined the term “sick societies” to describe cultures in which ways of life have become destructive their members. Consider the possibility that certain cultures may become pathogenic by virtue of their collapse and disintegration, with dire consequences for members (e.g., an inner-city slum area in which drugs, violence, disorders abound; a national culture that advocates war, violence, hate, and destruction as a means of defining its identity).

Ethnocentricity

Our “realities” are culturally constructed (Marsella, 1999), and because of this, it is easy for us to be ethnocentric in our assumptions and practices regarding psychopathology. “Ethnocentricity” refers to a tendency or inclination to perceive reality from the vantage point of our own cultural experience. Thus, we “center” or anchor our perceptions within a “biased” viewpoint, much as the term “egocentric” describes the tendency to see things only from our limited, individual perspective. The simple fact is that we are often unaware of and/or insensitive to alternative culturally constructed realities can lead to misguided intentions and behaviors. When ethnocentricity is combined with the power to control knowledge and opinion, the results are dangerous, because we are blinded to the possibilities of differences in our construction and experience of reality.

We must recognize that current knowledge about psychopathology as reflected in the widespread use of DSM-IV-TR (American Psychiatric Association, 2000) is based on assumptions about the nature of health and disease that are embedded within Western culture. The “power” assigned to Western psychiatry because of Western economic, political, and military dominance does not mean that Western psychiatry is “accurate”; rather, it is merely dominant. The position of dominance can lead to many problems, because people from differ-

ent ethnocultural groups are assessed, diagnosed, and treated according to the dominant viewpoint. Furthermore, even the research conducted is often framed with the dominant culture's assumptions and preferences for research design, data analysis, and data interpretation.

Ethnic Identity

As patients enter the Western psychiatric system as either ethnic/racial minorities or as patients within their own culture, but one dominated by a Western psychiatric system (e.g., Mexican patients in Mexico treated according to North American psychiatric approaches), the issue of ethnic identity becomes an essential consideration. The patient may belong to a particular ethnic/racial minority culture or be a resident in a mainstream culture but not be "identified" with that culture (e.g., Horvath, 1997; Yamada, 1998). Merely because the patient has a foreign last name and appearance (e.g., Japanese) does not mean he or she is not highly "Westernized" via acculturation processes (e.g., Chun, Organista, & Marin, 2002). The extent to which people are identified with a particular ethnic group, and engage in the attitudes, beliefs, and behaviors of that ethnic group, refers to their "ethnic identity" (Marsella & Kameoka, 1989). There are numerous ways to assess "ethnic identity" (see Dana, 1998; Ponterotto, Gretchen, & Chauhan, 2001; Yamada, Marsella, & Atuel, 2002). Some professionals have approached this topic from the viewpoint of "acculturation," or the extent to which a person may be embedded in a cultural context (e.g., Chun et al., 2002). It is noteworthy that DSM-IV-TR calls for an assessment of this variable in making a diagnosis as the first step in a cultural interview (American Psychiatric Association, 2000, p. 897).

CULTURAL INFLUENCES ON PSYCHOPATHOLOGY

The study of culture and psychopathology raises a number of basic questions that literally define the field:

- What is the role of cultural variables in the etiology of psychopathology?
- Are all mental disorders culture bound?
- What are the cultural variations in the rates and distribution of psychopathology? What

are some of the methodological considerations in conducting epidemiological research across cultures?

- What are the cultural variations in the classification and diagnosis of psychopathology (e.g., Mezzich et al., 1996; Paniagua, 2001)?
- What are the cultural variations in the phenomenological experience, manifestation, course and outcome of psychopathology?
- What are the cultural variations in standards of normality and abnormality?
- What psychometric factors must be considered in the assessment of psychopathology across cultures (e.g., Marsella, 2000b; Marsella & Leong, 1995)?

Space does not permit a detailed discussion of all these questions, but the first three questions are of sufficient importance to warrant discussion in this chapter.

Culture and the Etiology of Mental Disorders

Biological and Cultural Interaction

The role of cultural factors in the etiology of mental disorders is complex and varies as a function of the particular disorder and its plasticity. To the extent that a mental disorder may have a strong biological penetrance (e.g., certain forms of depressive disorders), the disorder will evidence great homogeneity across cultures because of biological similarity, and the influence may be minimal. However, to the extent that a mental disorder is influenced and shaped by learning and other contextual factors, thus having much more behavioral plasticity, acquired cultural factors may play a critical role. Expressions of a disorder may be more "homogenous" as a function of biological penetrance; yet even when the biological penetrance is extensive (e.g., Alzheimer's disease), it is still possible to see cultural variation. Figure 33.1 displays this thinking. Clearly, normal behavior is subject to the greatest cultural influence. But, even when there are severe neurological intrusions, culture still impacts the meaning, experience, and expression of disorder (Fabrega, 1995).

Cultural Factors in the Etiology of Mental Disorders

Cultural factors have been demonstrated to influence and shape mental disorders through a number of factors (Leighton & Murphy, 1961; Marsella, 1982, 1987, 2000a):

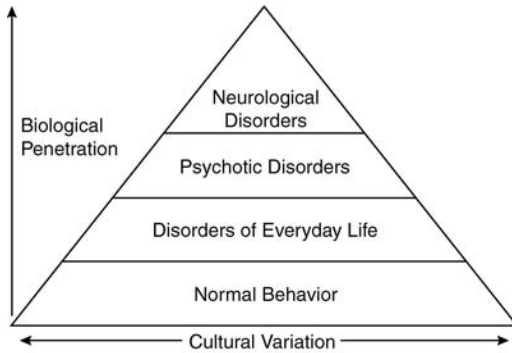

FIGURE 33.1. Cultural variations in mental disorders as a function of biological penetration and behavioral plasticity.

- Culture determines the types and parameters of physical and psychosocial stressors.
- Culture determines the types and parameters of coping mechanisms and resources used to mediate stressors.
- Culture determines basic personality patterns, including, but not limited to, self-structure, self-concept, and needs/motivational systems.
- Culture determines the language system of an individual, and it is language that assists us in the perception, classification, and organization of responses to reality.
- Culture determines the standards of normality, deviance, and health of an individual and society. It influences health ideology and attitudes, as well as treatment orientations and practices.

- Culture determines classification patterns for various disorders and diseases. In this respect, all mental disorders are culture-specific, and not simply those designated by Western professionals as exotic disorders.
- Culture determines the patterns of experience and expression of psychopathology, including factors such as onset, manifestation, course, and outcome.

Models of Cultural Etiology in Psychopathology

Among the conceptual approaches that have been advanced to explain cultural factors in the etiology of mental disorders, cultural disintegration and collapse has been advanced as a major hypothesis. This view was advocated quite early by Alexander Leighton (1959) in his classic work, *My Name is Legion*. Subsequent writings have elaborated on his contributions and suggested that general systems theory can be used to link stressors at the socioenvironmental level with the etiology of mental disorders at the individual level. Figure 33.2 displays these relationships (e.g., Marsella, Austin, & Grant, 2005).

Potential pathways between specific variables such as cultural collapse and disintegration, in which a culture's lack of coherence and integration eventually influences the mental health and well-being of members via intervening levels, are displayed in Figure 33.2. This is an important conceptual framework, because throughout the world today, as traditional cultures are faced with Westernization and other forms of rapid social change, members are left without a strong sense of ethnic identity and

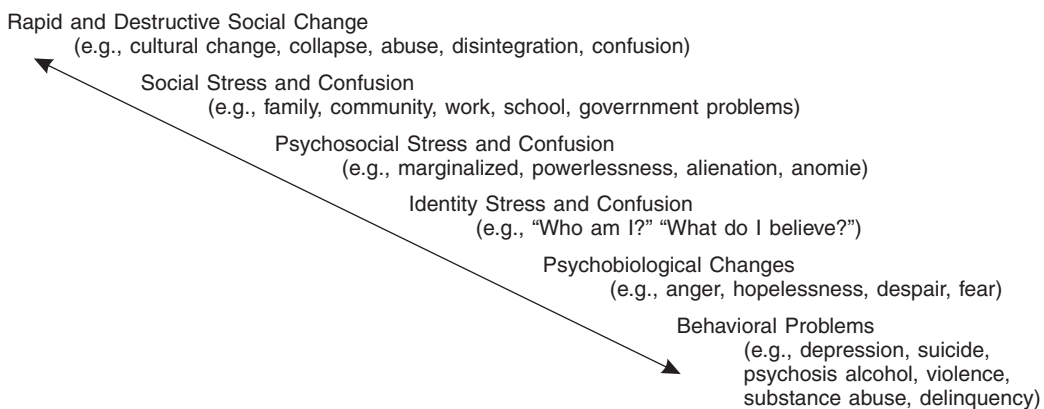

FIGURE 33.2. Sociocultural pathways to distress, deviance, and disorder.

continuity with their past, which results in conflict, confusion, and despair (e.g., Marsella et al., 2005).

Specific Sociocultural Variables Associated with Psychopathology

Numerous sociocultural variables have been posited as sources of psychopathology, including acculturation, urbanization, migration, and poverty. These variables have been primarily concerned with the etiology of psychopathology rather than its manifestations and/or courses and outcomes. All of these variables exercise their effects via stressors and stress variables. But each is unique in the specific stressors it embodies, and in the variations in the stress response that occurs. For example, acculturation and poverty stressors are both capable of eliciting stress states that can attain pathogenic levels. But each is unique in their stressor and stress-state parameters because of individual and cultural differences in coping resources. Nevertheless, they remain critical determinants of psychopathology that are rooted within cultural contexts (Marsella & Scheuer, 1993).

Acculturation

Acculturation refers to both the content and the process by which an individual from one ethnocultural group begins to assimilate and accommodate to the cultural traditions and ways of life of another—often contrasting—group. Acculturation can be a major source of stress, and as such is frequently considered a cause of maladaptation and maladjustment (Berry, 1997; Chun et al., 2002; Schmitz, 2003; Ward, 1997). The topic itself has been the subject of considerable debate and argument, especially with regard to its nature and measurement (Rudmin, 2003). Of special interest has been the yet unresolved issue of whether acculturation stress is associated with the onset of psychopathology, or whether it has little or no impact on the latter. For our purposes, we point out that the evidence is equivocal: Both sides have offered data to support their point of view.

Three things are needed at this point: (1) valid and reliable instruments for its assessment, (2) valid and reliable instruments for the assessment of psychopathology in the target groups, and (3) a clear description and understanding of the acculturative stresses involved,

and a conceptual linkage to a broad spectrum of psychopathology and to adaptive patterns. In other words, for some people, the interaction between acculturation stresses and traditional ways of life are clearly disruptive and can lead to psychopathology. However, others manage acculturation in such a way that they may have multiple cultural identities, completely assimilate into the new lifestyle, or even reject both.

Thus, the question becomes which individuals are most subject to psychopathology—those who maintain a traditional identity, those who embrace multiple identities, those who assimilate, or those for whom none of these apply? Furthermore, because of measurement problems, we must consider the possibility of the discrepancy among behaviors, attitudes, and a psychological sense of who one is or chooses to be. Conclusions are still being debated.

Urbanization and Psychopathology

Urbanization and urban life have long been proposed to be sources of psychopathology because of the multiple stressors imposed on urban residents (e.g., Marsella, 1998; Caracci & Mezzich, 2001) including stressors from overstimulation involved in crowding, noise-air-visual pollution, crime and violence, homelessness, poverty, and transportation. Clearly, rural life has its own share of stressors and rural dwellers should not be thought of as being immune to psychopathology. Because most of the world will soon be living in urban settings, the risks associated with urban life must be considered. Urban life is demanding, and the difficulties may exceed the abilities of individuals and groups to cope with the pressures.

Marsella (1998), in his review of the urbanization studies in the mental health literature, claimed that urban life stressors are numerous and varied (i.e., environmental, economic, sociological, psychosocial, and psychological) and as such are connected to a broad spectrum of psychopathological responses that often do not fit the standard psychiatric nomenclature (including misery, demoralization, apathy, indifference, alienation, trauma, distress and distrust, suspicion, dissatisfaction) but are nevertheless states of serious discomfort and maladjustment. Many social deviancies (i.e., substance abuse, alcoholism, divorce, crime, gambling) also emerge within the urban life

context. That these may also occur in non-urban settings does not exclude them from the pressures of urban life. Yet, even as we point this out, it is clear that urban life has many positive outcomes, including opportunities for new lifestyles, education, access to health care, and so forth. As was the case for acculturation, this topic is ripe for additional study.

Migration/Immigration

Migration/immigration has long been considered a major influence upon the onset of psychopathology (e.g., Marsella & Ring, 2003; Schmitz, 2003). Researchers have speculated about the possibility that migrants may actually be selected for particular forms of disorder or social deviancy, and this is reflected in the actual choice to migrate. Yet others have argued that the very best and strongest stock often migrates, and that the stress of the migration process and of acculturation is the source of psychopathology. The answer remains in debate. Certainly, if the pressures of migration and acculturation exceed the resources available for coping, then maladaptation and maladjustment may occur.

Culture shock, a syndrome of symptoms that includes paranoia, anxiety, somatic complaints, and a valorization of the home culture, is often found in sojourners and migrants during the early months of contact. Denial of opportunity and denigration of the migrant's self-esteem and sense of worth are also sources of discontent and distress. In our contemporary world, in which migration is now emerging as a major force for cultural contact, problems of acceptance are numerous. Ethnic and racial ghettos often develop as migrants are compelled to work for low wages and to live on the margins of acceptability and respect. This topic is in need of more research, because migration from East to West and from South to North brings millions of people from non-Western cultures to the Western world. Migrants seek hope and opportunity, but often find rejection and despair that lead to a breeding ground for anger, paranoia, and depression.

Poverty

Since the classic work on social class and mental illness by Hollingshead and Redlich (1958), it has long been accepted that lower social class individuals are at increased risk of mental ill-

ness. A recent meta-analysis of the literature (Lorant et al., 2003) supports the original conclusions. Low levels of education rather than low income per se has often been considered a key factor in these class differences. However, in a recent report on poverty and common mental disorders in developing countries, Patel and Kleinman (2003) concluded that factors such as the experience of insecurity and hopelessness, rapid social change, and risks of violence and poor physical health may better explain the vulnerability of the poor to common mental disorders. *Poverty and Psychology*, a recent volume edited by Carr and Sloan (2004), provides a detailed examination and analysis of the poverty experience, replete with its assaults on psychological and social well-being. In it, Moreira (2004) offers a specific review of the impact of poverty on mental health, including a discussion of the consequences of hegemonic globalization, marginalization, deprivation of power, trauma, low self-esteem, and nihilism. It seems clear that poverty imposes stresses of enormous proportion and frequency that exact a harsh toll on physical, mental, and spiritual health and well-being.

Culture-Specific (Culture-Bound) Disorders

The decision to list a series of "culture-bound" disorders in DSM-IV (American Psychiatric Association, 1994) called attention to a critical issue facing psychiatry and the study of psychopathology: Numerous previous publications had raised serious questions about these disorders and their implications for psychiatry (e.g., Simons & Hughes, 1985). DSM-IV (American Psychiatric Association, 1994) states the following about culture-bound disorders:

Culture-bound syndromes are generally limited to specific societies or culture areas and are localized, folk, diagnostic categories that frame coherent meanings for certain repetitive, patterned, and troubling sets of experiences and observations. There is seldom a one-to-one equivalence of any culture-bound syndrome with a DSM diagnostic entity. (844)

But are mental disorders universal or are they a function of the cultural context in which they occur? For some, this controversy has been attenuated by the answer that both are possible. Nevertheless, the recognition that cultural factors may shape the rates and expres-

sions of mental disorders represented a critical conceptual issue. Identifying a group of disorders with “non-Western” and “exotic” (some of these culture-bound disorders used to be called the “exotic” disorders, a testimony to our ethnocentric biases) names raised the issue of whether any disorder can escape cultural influence. And if this is the case, then is it not logical to assume that all disorders, including schizophrenia, depression, anxiety disorders, and so forth, are “culture bound.” The question must be asked: Is DSM-IV-TR, with its hundreds of disorders, a culturally biased work and as such, might it actually have destructive consequences when misapplied to cultures in which it is not applicable? Table 33.1 lists some “culture-bound” disorders.

Marsella (2000b, p. 407), listed a series of questions regarding culture-bound disorders:

1. Should culture-bound disorders be considered neurotic, psychotic, or personality disorders?
2. Should these disorders be considered variants of disorders considered to be “universal” by Western scientists and professionals (e.g., *susto* [soul loss] as merely a variant of depression)?
3. Are these disorders variations of common “hysteria,” “anxiety,” “depression,” or “psychotic” processes that arise in response to severe tension, stress, and/or fear, and present with specific culture content and expression?
4. Are there taxonomically different kinds of culture-bound syndromes (i.e., anxiety syndromes, depression syndromes, violence/anger syndromes, startle syndromes, dissociation syndromes)?

TABLE 33.1. Examples of Culture-Bound Disorders

Name	Definition and Cultural and Geographical Location
<i>Amok</i>	Sudden outburst of explosive and assaultive violence preceded by period of social withdrawal and apathy (Southeast Asia, Philippines).
<i>Ataque de nervios</i>	Uncontrollable shouting and/or crying. Verbal and physical aggression. Heat in chest rising to head. Feeling of losing control. Occasional amnesia for experience (Caribbean Latinos and South American Latinos).
<i>Hwa-Byung</i>	Acute panic, fear of death, fatigue, anorexia, dyspnea, palpitations, lump in upper stomach (Korea).
<i>Latab</i>	Startle reaction followed by echolalia and echopraxia, and sometimes coprolalia and altered consciousness (Malaysia and Indonesia).
<i>Koro (shook yong)</i>	Intense fear following perception that one’s genitalia (men/women) or breasts (women) are withdrawing into one’s body. Shame may also be present if perception is associated in time with immoral sexual activity (Chinese populations in Hong Kong and Southeast Asia).
<i>Phii pob</i>	Believes one is possessed by a spirit. Numbness of limbs, shouting, weeping, confused speech, shyness (Thailand).
<i>Pissu</i>	Burning sensations in stomach, coldness in body, hallucinations, dissociation (Ceylon).
<i>Suchi-bai</i>	Excessive concerns for cleanliness (changes street clothes, washes money, hops while walking to avoid dirt, washes furniture, remains immersed in holy river (Bengal, India—especially Hindu widows).
<i>Susto (espanto)</i>	Strong sense of fear that one has lost his or her soul. Accompanied by anorexia, weight loss, skin pallor, fatigue, lethargy, extensive thirst, untidiness, tachycardia, and withdrawal (Latinos in South and Central America, Mexico, and Latino migrants to North America).
<i>Taijin kyofusho</i>	Intense fear of interpersonal relations. Belief that parts of body give off offensive odors or displease others (Japan).
<i>Tawatl ye sni</i>	Total discouragement. Preoccupation with death, ghosts, spirits. Excessive drinking, suicide thoughts and attempts (Sioux Indians).
<i>Uquamairineq</i>	Hypnotic states, disturbed sleep, sleep paralysis, dissociative episodes and occasional hallucinations (Native Alaskans: Inuit, Yuit).

5. Do some culture-bound disorders have biological origins (e.g., *pibloktoq*—screaming and running naked in the Arctic snow—has been considered to result from calcium and potassium deficiencies because of dietary restrictions; *amok* has been considered to result from febrile disorders and neurological damage)?
6. Are all disorders “culture-bound” disorders given that no disorder can escape cultural encoding, shaping, and presentation (e.g., schizophrenia, depression, anxiety disorders)?

The last question continues to arouse controversy. If the answer is “yes,” then the implications for Western psychiatry are truly profound, for it indicates an inherent bias in its assumptions and practices from diagnosis to treatment. In so many ways, the culture-bound disorders issue confronts Western psychiatry with its most significant challenge.

Diagnosis and Classification

The American Psychiatric Association’s (2000) DSM-IV-TR provides clear-cut guidelines for diagnosing and classifying mental disorders when cultural boundaries are a concern. DSM-IV (American Psychiatric Association, 1994, pp. 843–844) guidelines suggest five major areas be addressed:

1. *Cultural identity of the individual* (e.g., ethnocultural identity, language abilities and preferences).
2. *Cultural explanations of the individual’s illness* (e.g., idioms of distress, meaning and perceived severity, any local illness categories used, perceived causes or explanatory models, current preferences for care).
3. *Cultural factors related to psychosocial environment and levels of functioning* (e.g., interpretations of social stressors, available social supports, levels of functioning and disability).
4. *Cultural elements of the relationship between the individual and the clinician* (e.g., note differences in culture and status of patient and clinician, and possible problems these differences may present, including problems regarding perceived normality, symptom expression, communication).
5. *Overall cultural assessment for diagnosis*

and care (e.g., how the cultural formulation impacts diagnosis and care).

These guidelines articulate and anticipate many of the problems that one must face when seeking to diagnose and classify an individual within a cross-cultural context. The risks of error are obvious. Without understanding a person’s cultural identity and experience, errors in diagnosis may lead to destructive treatments. It is necessary to have a firm understanding of the standards of normality and abnormality for that person and his or her culture and, especially, particular models of health and illness (see Alarcon, Bell, et al., 2002; Canino, Canino, & Arroyo, 1997; Mezzich et al., 1996; Mezzich & Fabrega, 2001; Paniagua, 2001; Rogler, 1997).

It is also important to note that virtually every ethnocultural group has its own diagnostic and classification system for psychopathology and social deviancies. These systems often address disorders that appear to be “similar” to Western disorders, such as PTSD (e.g., Fox, 2003). Yet we are once again faced with the challenge of “decontextualizing” a disorder when we assume that it is similar. In Hispanic culture, is *ataques de nervios* simply an anxiety disorder, or is *susto* simply a depressive disorder? In Japanese culture, is *shinkeishitsusho* simply a variant of neurasthenia, a popular 19th-century Western diagnostic category (Ohnuki-Tierney, 1984)? For example, consider the case of Samoans, who speak of four major categories of mental illness (see Clement, 1982):

1. *Ma’i o le mafau’fau* (physical brain abnormalities)
2. *Ma’i aitu* (spirit possession)
3. *Ma’i valea* (strange, severe, and stupid, improper behavior)
4. Excess emotion:
 - *Ma’i ita*—anger, rage
 - *Ma’i manatu*—sadness, grief
 - *Ma’i popole*—worry

Do the apparent similarities or approximations indicate that the disorder has the same etiology, onset, expression, course, and outcome as disorders in the Western world? The answer in our opinion is “no!” The overt appearance of a disorder does not mean that the causes, experience, or pattern are the same. How can we separate a disorder from the very psyche in which

it is construed and the very social context in which people respond to it?

The separation of mind and body introduces a dramatic difference in the conceptualization of psychopathology, especially with regard to its etiology and expressions. For example, in her excellent discussion of Japanese concepts and categories of mental illness, Ohnuki-Tierney (1984) wrote:

When the Japanese postulate that *ki* (mind, spirit) is responsible for illness, they really do not mean psychogenesis. When they say *yamai wa ki kara* (illness from one's mind), they refer to physical illnesses resulting from worries and other psychological propensities that have a negative effect on the body. When they use the lable *ki no yamai*, they refer to a mild negative psychological state, such as a mild case of hypochondria. In both expressions, *ki* (mind, spirit) refers to a psychological state in the simple sense of the word. It does not refer to either "psychological problems" or "psychodynamics" as these terms are used in the United States. (p. 75)

Epidemiology of Mental Disorders

One of the most obvious questions about mental illness is whether there are cultural and international variations in the rates and distribution of mental illness. But because of the complexities involved in obtaining data to inform this question, any answers must be very tentative and subject to careful scrutiny. Even case identification, which seems like such a straightforward activity, can be filled with problems depending upon the source of the data, the measurement criteria, and the biases of the researcher. As we have pointed out, numerous issues are involved in the assessment and diagnosis of mental illness across cultures. These issues make valid data collection a difficult task. Marsella (1979) and Marsella, Sartorius, Jablensky, and Fenton (1985) listed criteria that must be met before data can be compared. They stated that the comparative epidemiological studies must do the following:

1. Use relevant ethnographic and anthropological data in designing an epidemiological study, especially in determining what constitutes a symptom or category or a case.
2. Develop glossaries of terms and definitions for symptoms and categories.
3. Derive symptom patterns and clusters using multivariate techniques rather than relying on simple a priori clinical categories.
4. Use similar/comparable case identification and validation methods.
5. Use culturally appropriate measurement methods that include a broad range of indigenous symptoms and signs that can be reliably assessed.
6. Establish frequency, severity, and duration baselines for indigenous and medical symptoms for normal and pathological populations.

These steps do not guarantee accuracy, but they do call attention to the complexities involved in conducting comparative epidemiological studies of mental illness. Failure to consider them can lead to destructive consequences for cultures under study, because they may either overestimate or underestimate actual rates leading to faulty policy decisions and misleading stereotypes.

The World Health Organization (2004) initiated a survey of the prevalence, severity, and treatment of DSM-IV mental disorders in six less developed countries and eight developed countries using door-to-door surveys of 60,463 community adults in the Americas, Europe, the Middle East, Africa, and Asia. Psychiatric assessments were conducted using the WHO world Mental Health Composite International Diagnostic Interview (WMH-CIDI), a fully structured, lay-administered psychiatric diagnostic interview. Results revealed that the prevalence of having a disorder during the previous year varied widely, from low rates of 4.3% in Shanghai, China, and 4.6% in Nigeria, to the highest rate of a 26.4% in the United States. Higher rates of anxiety were found in the United States, France, and Lebanon, and lower rates of anxiety were found Shanghai, Beijing, and Nigeria. The study also reported that 35.5–50.3% of serious cases in developed countries and 76.3–85.4% in less developed countries received no treatment in the 12 months prior to the interviews.

The profound variations in rates of disorder across developed and less developed countries raise interesting questions about the reasons for the results. Although it is possible that these rates accurately reflect differences because of a number of reasons related to stress levels, coping resources, and even genetic variations, the risk of bias in content and process of the actual interviews cannot and should not be ignored. For example, the content of the interview is clearly Western (e.g., anxiety, mood) and does

not include indigenous examples of disorders. It is possible that different results might emerge if disorders were keyed to specific locations and the study examined rates of Western disorders and indigenous disorders in the less developed countries. Comparison data must meet stringent criteria for case recognition and inclusion, or one group may be seen as pathological and another as salutogenic, when the opposite may be true. The criteria listed previously for valid epidemiological studies must be considered.

Weiss (2001) proposes a culturally sensitive model of illness representations for epidemiological studies and Weiss, Cohen, and Eisenberg (2001) offer an integrative framework for cross-cultural epidemiological studies that captures both the complexity and critical consequences of epidemiological studies. In a similar vein, Alarcon et al. (2002) wrote:

A crucial feature of the cultural epidemiologic context in relation to diagnosis is who decides on the values and priorities that transform findings into authoritative evidence. The cultural representation of mental illness requires a categorical identification but also a narrative account and a full assessment of the social context in which illness occurs. (p. 234)

CULTURE AND VARIOUS FORMS OF SERIOUS PSYCHOPATHOLOGY

Schizophrenia across Cultures

Among all the forms of mental disorder, schizophrenia has been considered to be the least influenced by cultural factors. Yet this assumption is highly questionable given the fact that there are considerable variations in the rates of schizophrenic disorders and considerable differences in its experience, course, and outcome (e.g., Jablensky et al., 1992; Marsella, Suarez, et al., 2002; Jenkins, 1998; Barrio et al., 2003; Jenkins & Barrett, 2004). The assumption is that because schizophrenia is considered to have a neurological (chemical and/or structural) basis, cultural variations should be minimal. But research indicates that the very conceptualization of schizophrenia in the West may be a major source of impediment to understanding and curing it. Indeed, despite the fact that schizophrenia research in the West has advanced different sites of pathology, different etiologies, different expressions, and different treatment responsivities, we continue to use the

term, thus inviting confusion for both the public and professionals.

Research has shown that the expression of psychotic symptoms can be embedded in the patient's sociocultural context reflecting strongly held values and beliefs (Suhail & Cochrane, 2002). For instance, in the United States a triethnic study of psychotic symptoms assessed with a structured interview, African Americans were more likely to report higher hallucinatory behavior and suspicion scores than were European Americans, whereas European Americans exhibited more severity than African Americans in the excitement symptom score, and Latinos reported higher rates of somatic concern than both European Americans and African Americans (Barrio et al., 2003). In another triethnic study, which included a community outpatient sample, that European Americans had a more symptomatic profile than did African Americans and Latinos when assessed with standardized assessment tools (Bae, Brekke, & Bola, 2004; Brekke & Barrio, 1997). One potential explanation is that content experienced as culturally syntonic may be less likely to be reported as a distressing psychiatric complaint by certain ethnic/minority patients (Guarnaccia, Parra, Deschamps, Milstein, & Argiles, 1992).

Distinguishing between culturally appropriate and pathological content of symptoms to ensure that best practices are followed is facilitated by careful consideration of the manifestation and expression of distress (American Psychiatric Association, 1994; Gaines, 1995). Table 33.2 lists some of the sociocultural determinants of "schizophrenia" that have been advanced in the research literature, and Table 33.3 summarizes some of the many reasons why the course and outcome of schizophrenia varies across cultures (for reviews of the empirical literature, see also Jablensky et al., 1992; Marsella, Suarez, et al., 2002).

Kelly (2005) has called attention to the growing interest in the role of social, cultural, economic, and political factors in influencing clinical and outcome aspects of schizophrenic disorders:

Despite clear evidence of a substantial biological basis to schizophrenia, there is also evidence that social, economic and political factors have considerable relevance to the clinical features, treatment and outcome of the illness. Individuals from lower socio-economic groups have an earlier age at first presentation and longer durations of untreated illness, both of which are associated with poor out-

TABLE 33.2. Some Sociocultural Determinants of Schizophrenia

-
1. Cultural concepts of personhood and the related implications of this for individuated versus unindividuated definitions of selfhood and reality.
 2. Cultural concepts regarding the nature and causes of abnormality, discomfort, disorder, deviance, and disease, and those regarding the nature and cause of normality, health, and well-being.
 3. Cultural concepts and practices regarding health, and medical care and prevention; attitudes toward illness and disease.
 4. Cultural concepts and practices regarding breeding patterns and lineages.
 5. Cultural concepts regarding prenatal care, birth practices, and postnatal care, especially in areas such as nutrition and disease exposure.
 6. Cultural concepts and practices regarding socialization, especially family, community, and religious institutions, structures, and processes.
 7. Cultural concepts and practices regarding medical and health care, especially with regard to the number and types of healers, doctors, sick-role statuses, etc.
 8. Cultural stressors such as rates of sociotechnical change, sociocultural disintegration, family disintegration, migration, economic development, industrialization, and urbanization.
 9. Culturally related patterns of deviance and dysfunction including trauma (PTSD), substance abuse, violence and crime, social isolation, alienation/anomie, and the creation of pathological and deviant subcultures.
 10. Cultural stressors related to the clarity, conflicts, deprivations, denigrations, and discrepancies associated with particular needs, roles, values, statuses, and identities.
 11. Cultural stressors related to sociopolitical factors such as racism, sexism, and ageism and the accompanying marginalization, segmentalization, and underprivileging.
 12. Cultural resources and coping patterns, including institutional supports, social networks, social supports, and religious beliefs and practices.
 13. Cultural exposure to various risk conditions, such as communicable diseases (e.g., viruses), toxins, dietary practices, population density, poverty, and homelessness.
-

TABLE 33.3. Potential Reasons for More Negative Course and Outcome of Schizophrenia (Psychotic Disorders) in Developed Countries

-
1. Schizophrenia is considered to be a biological disease that is relatively immutable to life circumstances.
 2. Causes of schizophrenia are considered to be within the individual. Personal control and responsibility are assumed.
 3. High social rejection and stigma attached to schizophrenia.
 4. Individual burdens are demanding, because family resources are not often present.
 5. Patient is often hospitalized and isolated from family and community. Custodial care, in disguised forms, is present.
 6. Financial incentive to continue the sick role (i.e., disability payments, insurance payments) are numerous and easily available.
 7. Stressors are numerous and supports are minimal.
 8. Competency levels required for normal functioning are very high and very demanding upon social and intellectual skills and abilities (e.g., bank accounts, tax forms, housing, automobile maintenance, literacy skills).
 9. Religious systems and spiritual concerns are often inadequate.
 10. Comorbidities are numerous and complex (e.g., substance abuse, alcohol, trauma).
 11. Treatments are primarily medical and invasive, with compounding iatrogenic effects (e.g., tardive dyskinesia).
 12. Insensitivities to class and cultural differences between patient and professional abound with resulting communication problems.
-

Note. The inverse of these conditions is considered to be present in developing countries, accounting for their positive outcomes.

come. Individuals with schizophrenia are over-represented in the homeless population. Migration is associated with increased rates of mental illness, including schizophrenia, and this relationship appears to be mediated by psycho-social factors, including difficulties establishing social capital in smaller migrant groups. Individuals with schizophrenia are substantially over-represented amongst prison populations, and imprisonment increases the disability and stigma associated with mental illness, and impedes long-term recovery. The adverse effects of these social, economic and societal factors, along with the social stigma of mental illness, constitute a form of “structural violence” which impairs access to psychiatric and social services and amplifies the effects of schizophrenia in the lives of sufferers. As a result of these over-arching social and economic factors, many individuals with schizophrenia are systematically excluded from full participation in civic and social life, and are constrained to live lives that are shaped by stigma, isolation, homelessness and denial of rights. There are urgent needs for the development of enhanced aetiological models of schizophrenia, which elucidate the interactions between genetic risk and social environment, and can better inform bio-psycho-social approaches to treatment. (p. 721)

It is clear that in spite of extensive research, biological models of schizophrenic disorders continue to be inadequate in accounting for the many and varied patterns of symptomatology, course, outcome, and responsiveness to treatment. The complexity of this spectrum of disorders appears to require a biopsychosocial approach in which cultural factors are considered to be a critical determinant of these clinical parameters.

Culture and Depressive Experience and Disorder

Another popular area of inquiry has been the relationship between culture and depressive experience and disorder. This topic has been the subject of extensive theoretical and clinical publications (e.g., Kleinman & Good, 1985; Marsella, Kaplan, & Suarez, 2002; Andrade et al., 2003). Marsella, Kaplan, et al. (2002) note that depression has long been a major topic of concern in Western medical history:

Depressive experience and disorder have long been a source of concern in Western cultural traditions. Hippocrates (330–399 B.C.E.) included melancholia within his tripartite classification of disorders (i.e., mania, melancholia, phrenitis). He considered its cause to be a function of excessive

black bile. Stanley Jackson (1986), in his scholarly book on the topic, *Melancholy and Depression: From Hippocratic Times to the Present*, points out that the term “melancholy” was first used in ancient Greece to describe a disorder characterized by fear, nervous conduct, and sorrow. By the fourth century A.D., the Christian Church had begun to shape the concept of melancholy with its use of the term *acedia* to designate a cluster of feelings and behaviors associated with “dejection” (Jackson, 1986). The condition was often associated with religious fervor among monks and others that practiced isolation and self-denial. It came to mean sluggishness, lassitude, torpor, and non-caring, as well as those emotions associated with *tristitia* (i.e., sadness) and *desperatio* (i.e., despair). . . . “Melancholy” was used extensively in Europe until the 17th century when the term “depression” began to acquire currency. The promotion of “melancholy” as a major mood disorder, dysfunction, and problematic characterological orientation was assisted by the publication of Robert Burton’s tome, *The Anatomy of Melancholia*, published in 1652. This book gained immediate and widespread popularity and remained a vital source of clinical insight and acumen on mood problems for subsequent centuries because of its encyclopedic coverage of the topic. (p. 50)

Emerging social conditions now suggest that depressive disorders are becoming the world’s foremost psychiatric problem because of global challenges such as war, natural disasters, racism, poverty, cultural collapse, aging populations, urbanization, and rapid social and technological changes. The burdens from these challenges often exceed individual and social resources necessary for mediation (Marsella, Kaplan, et al., 2002). Some writers, such as Murray and Lopez (1996), contend that within a few decades, depression may be the greatest cause of disability worldwide. Under these circumstances, it is clear that we must make every effort to grasp the nature and consequences of this disorder(s). And it also clear that we must consider cultural contributions to depressive experience and disorder.

Marsella (1985, 1987) notes that the Western experience with depressive disorders may be a function of Western preoccupation with guilt, individualism, self-structure, self-control, personal responsibility, and an “abstract” language structure that creates distance between the person and his or her experience through language and self. In contrast, the Eastern experience of depression tends to reflect the integrated conception of mind and body as one and

is portrayed through somatic symptoms rather than feelings of sadness (Marsella, Kinzie, & Gordon, 1973; Kleinman, 2004; Kleinman & Good, 1985).

In a fascinating study in Australia, Gattuso, Fullagar, and Young (2005) examined the construction of depression promoted in popular women's magazines (e.g., celebrity stories, advice columns, resource links) and contrasted this with governmental health materials promoting a "depression" literacy. They found that the latter privileges biomedical and psychological expertise and help-seeking behavior, whereas the former emphasizes self-management and biological expertise. The authors also contend the government materials do not emphasize gender differences and fail to discuss social inequities. What is so important about this study is its recognition of the critical role that communication media may play in favoring certain constructions over others and in shaping views that may or may not be held among populations—an example of cultural influences.

The very way we come to know the world about us (i.e., epistemology) becomes a mediator of depressive experience and disorder. Here, the possibility that cultural variations in the very nature of definition and construction the self (also personhood) mediates depressive experience and disorder become apparent. This viewpoint emphasizes the role of the subjective experience for psychopathology, because at this level the experiential meanings of both health and disorder become apparent (e.g., Jenkins, 1998; Jenkins & Barrett, 2004). In addition to Jenkins and Barrett (2004), many other writers acknowledge cultural variations in self, subjectivity, and emotion, and the implications this may have for behavior (e.g., Csordas, 1994; Kanagawa, Cross, & Markus, 2001; Kitayama, Markus, Matsumoto, & Norasakkunkit, 1997; Marsella, 1985; Nathan, Marsella, & Horvath, 1999).

Yet another variable that must be considered is social class and all that this implies for different racial and ethnic minorities. A recent meta-analytic review of social class by Lorant et al. (2004) concluded that depression is inversely related to social class (i.e., the lower the class, the higher the rate of depression). This is not unexpected because it highlights how certain social conditions such as poverty, racism, powerlessness, and marginalization can contribute to the onset of despair, hopelessness, and helplessness (Marsella, 1997). Marsella stated:

Mental health is not only about biology and psychology, but also about education, economics, social structure, religion, and politics. There can be no mental health where there is *powerlessness*, because powerlessness breeds despair; there can be no mental health where there is *poverty*, because poverty breeds hopelessness; there can be no mental health where there is *inequality*, because inequality breeds anger and resentment; there can be no mental health where there is *racism*, because racism breeds low self-esteem and self denigration; and lastly, there can be no mental health where there is *cultural disintegration* and destruction, because cultural disintegration and destruction breed confusion and conflict. (Marsella, 1997, quoted in Marsella & Yamada, 2000, p. 10)

These words embody the complex challenges we face as mental health scientists and professionals. In a world in which medications have become commonplace, we must not forget the structural problems that contribute to depressive experience and disorder.

The stigma of depression can also be a cultural barrier to diagnosis and treatment in many cultures (e.g., Docherty, 1997). Despite an awareness of the urgent need for culturally sensitive interventions to address depressive disorders, relatively little research has been conducted. An NIMH-sponsored workgroup established to develop recommendations to improve access to preventive and treatment options for depression (Hollon et al., 2002) recommended increasing the involvement of minority researchers and developing user-friendly and nontraditional delivery methods to increase access of racial/ethnic minority groups to evidence-based interventions. A similar workgroup considered strategies that use social marketing research to increase access to services to ethnic and minority populations with affective disorders (Bruce, Smith, Miranda, Hoagwood, & Wells, 2002). Wells, Miranda, Bruce, Alegria, and Wallerstein (2004) also reported on an approach directed toward increasing access to mental health service interventions in diverse communities. There remains a need for special attention to disparities in access to treatments among vulnerable populations, such the youth (Richardson, DiGiuseppe, Garrison, & Christakis, 2003), older adults (Crystal, Sambamoorthi, Walkup, & Akincigil, 2003), and refugees and displaced victims of war and natural disaster (Carballo et al., 2004).

Culture, Alcoholism, and Substance Abuse

In a review of the literature on cultural aspects of alcoholism and substance abuse, Marsella (2004) noted that although the use and abuse of alcohol and various substances are quite old (e.g., mead or fermented honey may date back to 4000 B.C.E.; opium and hallucinogen use may date back to 1000 B.C.E.), misuse of both alcohol and substances has become a serious source of societal problems (e.g., Heath, 1995; Helzer & Canino, 1992; Staussner, 2001). The multiple cultural factors in alcohol and substance use include rituals (e.g., peyote cults), health and medications, religious experiences, social lubricants, occupational and group membership functions (e.g., military, police, factory workers), sensation seeking, commerce, and pleasurable states.

Cultural factors in the use and abuse of alcohol and various substances often assume location contexts that serve to reinforce and value them. For example, consider the fact that college fraternities now constitute one of the highest risk subcultures for the promotion of alcoholism and substance abuse. Other high-risk subcultures include the military, the entertainment industry, and the ubiquitous cocktail hour. These cultural activity settings often promote excesses in alcohol and substance use. American popular culture may also be considered a source for alcoholism and substance abuse, through its use of mass advertising, lobbying, and information groups supported by industries; corporations that produce alcohol and tobacco; positive portrayal of substance and alcohol use through celebrity and enter-

tainment media; the promotion of subcultures that endorse social deviancies (e.g., violent rap music cultures, bars/pubs); and the promotion of positive images of substance abuse and alcohol use (e.g., the Marlboro Man, Joe Camel, beer drinkers as macho men and sensual women, sexual images).

In addition, high-stress situations, such as being homeless, have been associated with increased rates of substance use (VanGeest & Johnson, 1997). Although immigrants as a group experience numerous daily stressors, they have been shown to misuse substances to a much lesser degree than do native-born citizens (Johnson, VanGeest, & Cho, 2002). As immigrants acculturate and adapt to the “American” lifestyle, their use and misuse of substances rises (Johnson et al., 2002; O’Hare & Van Tran, 1998). This rise in substance abuse was noted whether degree of acculturation was measured in terms of learning to speak English or length of residence (Gfroerer & Tan, 2003). Despite evidence of the negative ramifications of American popular culture investigating the characteristics of immigrants rather than studying the components of the American way of life that may be contributing to substance abuse has remained the focus of the literature.

The complex ecology of American popular culture that supports and maintains alcoholism and substance abuse is displayed in Figure 33.3, which points out that popular cultures, much like ethnocultural groups, can also influence psychopathology in the form of various personal and social deviancies. A WHO (2004) study comparing prevalence rates of substance abuse during the previous year across 14 coun-

← Ethos	Subculture	Location	Rewards →
Self-Indulgence	Celebrity	Home	Addiction
Hedonism	Advertising	School/College	Pleasure
Immediacy	Parents	Parties/Proms	Escape, Drop Out
Conformity	Rock Culture	Clubs	Dulling
Macho	Teen Culture	Parks	Liberation
Sexualism	Military	Bashes	Social Acceptance

Risk Behaviors	Fraternities	Concerts	Punish Parents
Competition	Sororities	Bars	Status

FIGURE 33.3. The complex ecology of alcoholism and substance abuse: Interactions/reciprocity of cultural ethos, subcultures, locations, and rewards.

tries found the Ukraine to have highest rates (6.4%) and Italy, Spain, and France to have the lowest rates (0.1–0.7%). However, we need to consider instrument and procedural bias need before we accept these results.

Based on the research and clinical literature on cultural considerations in alcoholism and substance abuse (e.g., Marsella, 2004), a number of conclusions can be reached:

- The causes and functions of alcohol and substance use and abuse vary according to culture, society, and historical period (e.g., ritual, nutrition, pleasure, economic scale).
- As alcohol and substance use and abuse become a problem (i.e., medical health, safety, economic loss) in a given setting, laws and other social restrictions and guidelines emerge to control and limit problems (e.g., prohibition, labeling a person a “drunk”).
- Substantial cultural, local, and national variations characterize the patterns of use and endorsement of alcohol and substances.
- The particular kinds of alcoholic beverage and substances that emerge in a given setting and time are a function of available substances (e.g., mushrooms, rice, wheat), technology (e.g., distillation), and particular aversions and/or preferences.
- The definition and meaning of “abuse” can vary according to “legal,” “medical,” “moral,” and/or “normative” perspectives and across cultures and settings.
- Understanding alcoholism and substance abuse may require new conceptual models that consider the complex ecology of the substance, location, people present, functions, and antecedents–consequences of use and abuse.
- As cultures and societies grow, complex laws of supply and demand emerge that may have international implications (e.g., external suppliers of cocaine) as new sources and substances become available.
- Certain types of substances may come into being for one purpose but end up serving others for which they were not intended (e.g., opium, morphine, heroin).
- Cultures often have political, economic, and social forces that encourage the use of alcohol and substances in spite of their known dangers (e.g., alcohol industry, tobacco industry). These forces, driven by profit, can shape public views of alcoholic beverages and substance abuse.

- Changes in alcohol and substance use and abuse, patterns and consequences occur so rapidly that research is often dated.

CONCLUSIONS AND SUMMARY

After many years of being ignored and marginalized, both mental health professionals and researchers have come to accept the important role of cultural factors in the etiology, expression, manifestation, distribution, course, and outcome of all forms of psychopathology and social deviancy. This acceptance is now codified in DSM-IV-TR (American Psychiatric Association, 2000) in the form of both warnings to clinicians to consider cultural variables and a diagnostic heuristic (pp. 897–903) and list of culture-bound disorders. To a large extent, this acknowledgment has led to a widespread concern about among practitioners and scientists alike about teaching and practicing cultural competence.

The facts were clear! Cultural factors had for too long been ignored at the expense of the patient’s welfare and an accurate, valid portrayal and understanding of psychopathology. As the research progressed, it became clear that psychopathology, like normal behavior, evidenced considerable variations. The etiology of disorders was seem to be linked to a broad spectrum of sociocultural conditions, including cultural disintegration and collapse, poverty, crowding, rapid social change, acculturation, and a host of other forces that increased stress levels in the face of inadequate personal and collective resources. It also became clear that mental health could not be achieved apart from the sociopolitical context of life, in which forces such as racism, sexism, and political oppression fostered marginalization, powerlessness, and lack of privilege. Individuals and groups compelled to live on the margins of society would inevitably be faced with stress levels that would lead to distress, dysfunction, deviancy, and disorder.

Rates and expressions of psychopathology were also demonstrated to vary across ethnocultural boundaries; comparative studies used matched diagnoses, matched samples, international surveys, and factor-analytic research strategies. What emerged for depressive disorders was a variation in the expression that included limited guilt, existential despair, and low self-esteem, all of which were hallmarks of the disorder in the Western world. Even in the

schizophrenic disorders, long considered to be universal disorders tied to genetic and biological substrates, ethnocultural and national variations emerged in rates, patterns, course, and outcome. For ethnic minorities in the United States, and for the entire international community, the consideration of cultural factors introduced a new hope that eradication of diagnostic inaccuracies and erroneous treatments would lead to improvements in the accessibility, availability, and acceptability of care and service provision.

Today the study of culture and psychopathology has emerged as a popular area of inquiry, with its own journals and books, conferences, and professional and scientific leaders. To a large extent, many of the latter are ethnic minority or international figures, and this is good, for it ensures that issues ignored for so long now inspire a new level of awareness and a new response. The fact of the matter is that the study of culture and psychopathology has revealed how our clinical knowledge and practices are often shaped not by science but by social and political forces that advance particular views based on their ethnocentric or gender biases. We are not free of this risk, but now that we are much more aware of it, we are capable of responding with corrective and preventive measures.

PART VII

COMMENTARIES
FROM TWO PERSPECTIVES

CHAPTER 34

An Anthropological Perspective

The Revival of Cultural Psychology— Some Premonitions and Reflections

RICHARD A. SHWEDER

The publication of this handbook is of historical importance for the field of cultural psychology, and it is a fitting and useful form of acknowledgment of an intellectual revival or take-off of interdisciplinary research interests that began about 25 years ago. It is also a welcome opportunity to take stock and imagine future possibilities for creative investigations of diversity in human mentalities (the different things people know, think, want, feel, and value) across distinguishable culture-dependent groups. Although the volume is surely going to become a canonical text for anyone who has been engaged in or wishes to become part of the lively ongoing conversation that began to emerge in the early 1980s at the interface of social psychology and anthropology, it will certainly also interest developmental psychologists, cognitive psychologists, philosophers, and even linguists. Robert LeVine's chapter (Chapter 2, this volume) tells a story of academic ancestry that must read like ancient history to contemporary social psychologists doing work in cultural psychology (and an even deeper history going back many centuries, one

that all of us should know, can be found in Gustav Jahoda's [1993] *Crossroads between Culture and Mind*). So it is a very old conversation, but a new one as well, and one that has grown in depth and intensity over the past couple of decades.

Increasingly, this renewed conversation has been gaining widespread recognition. One is actually heartened to read the five-paragraph entry under "Cultural Psychology" that appears in Wikipedia, not only because that consensus-seeking online encyclopedia acknowledges the discipline but also because they more or less get it right. Here is all or part of the lead sentence from each of the five paragraphs: "Cultural psychology is a field of psychology which contains the idea that culture and mind are inseparable"; "Cultural psychology has its roots in the 1960s and 1970s but became more prominent in the 1980s and 1990s"; "Cultural psychology is distinct from cross-cultural psychology in that cross-cultural psychologists generally use culture as a means of testing the universality of psychological processes rather than determining how local cultural practices

shape psychological processes”; “Cultural psychology research informs several fields within psychology, including social psychology, developmental psychology, and cognitive psychology”; “One of the most significant themes in recent years has been cultural differences between East Asian and North Americans in attention (Masuda & Nisbett, 2001), perception (Kitayama, Duffy, Kawamura, & Larsen, 2003), cognition (Nisbett, Peng, Choi, & Norenzayan, 2001) and social-psychological phenomena such as the self (Markus & Kitayama, 1991).” They also write: “So whereas a cross-cultural psychologist might ask whether Piaget’s stages of development are universal across a variety of cultures, a cultural psychologist would be interested in how the social practices of a particular set of cultures shape the development of cognitive processes in different ways.” Perhaps the authors of the entry do go a bit overboard in associating cultural psychology with the view that “there are no universal laws for how the mind works,” but for the most part they get the point.

Indeed, my own earliest anticipation of a cultural psychology revival—at the time it was little more than a premonition—does go back to the 1960s. In 1964 the anthropologists A. Kimball Romney and Roy D’Andrade published an influential special issue of the *American Anthropologist* titled “Transcultural Studies in Cognition.” That collection of essays, originally prepared for an interdisciplinary Social Science Research Council conference on culture and intellectual processes held in Mexico in the spring of 1963, was an intimation that something new and interdisciplinary—on the frontiers of anthropology, psychology and linguistics—might soon be in the air. Best of all, the publication included a “Summary of Participants’ Discussion,” which contained some rather eye-opening (and even entertaining) transcripts of verbal exchanges (and sallies) between several social psychologists and several cultural anthropologists. Comments and quips included:

In using the semantic differential, people are forced to evaluate objects, and apparently there is consistency in the way in which they respond. I don’t understand what the meaning of this consistency is in terms of the culture in which it occurred. And until I understand it, I don’t see any point in comparing across cultures. You say that these factors are related to “visceral reactions”—then perhaps what this consistency means is that

cultural differences have been wiped out and only a common animal reaction remains. —anthropologist William Sturtevant, critiquing psychologist Charles Osgood (p. 238)

No, just the reverse. We are trying to find a framework of similarities within which we can observe more meaningfully and more rigorously real differences. Then we can be sure that these are real differences and not just artifacts of the language being used. —psychologist Charles Osgood (p. 238)

If you did investigate which adjectives went together in a language and culture which you know, do you doubt seriously that you would find three dimensions similar to evaluation, potency, and activity? —psychologist Fred Strodtbeck, addressing anthropologist Sturtevant (p. 238)

I don’t know. And the reason it bothers me is that it seems so artificial to force people to tell you whether “Wednesday” is “good” or “bad.” And I don’t understand what significance any consistency you may get in forced tasks such as this has for understanding a culture. —anthropologist William Sturtevant (p. 238)

Why is it more arbitrary to employ the probes used in the semantic differential than it is to employ the “kind of” or “part of” questions [Charles] Frake uses? What is there unique about one kind of questioning which makes it arbitrary? —psychologist Charles Osgood (p. 238)

I think we are doing the same things for different reasons. We are both asking people questions and getting answers. But one difference is that if people laugh at one of my questions, I throw away the question. If people laugh at what you ask, you force an answer and say, “Come on, boys, now this is serious.” What I would like to know is, “How much force is legitimate, and is the amount of force a variable to be taken into consideration?” —anthropologist Charles Frake (p. 238)

This is the narrow line we have tried hard to walk. That is, in order to get comparability, we have had to use enough control over the general context in which the data is elicited to obtain some reasonable security of equivalence. The problem, then, is to make sure that the kind of control that is exercised for that purpose can in no way influence the substantive relationships within the material. . . . —psychologist Charles Osgood (p. 238)

In their summary of the conversations among the conference participants, the editors Roy D’Andrade and Kim Romney (two very multidisciplinary graduates of the Harvard University Department of Social Relations)

tried to comprehend the disciplinary tensions between the anthropologists and the psychologists by drawing a distinction between the study of “codes” (associated with anthropological research) and the study of “intellectual processes” (associated with psychological research). They imagined a hypothetical research project in which anthropologists and psychologists go off together hand in hand to study ordinary game-playing behavior in games such as chess, checkers, or baseball, but end up parting ways by asking very different questions (e.g., “What are the rules of this game?” vs. “Which intellectual abilities differentiate winning players from losing players?”) and end up developing two very different theories of psychological functioning and methods of research. D’Andrade and Romney elaborated on this imagined contrast. Anthropologists, they suggested, tend to study socially learned codes, rules, and meanings for the interpretation of a behavior (remember Clifford Geertz’s [1973] famous example of the “blink [or was it a ‘wink’?] of an eye”); and for the anthropologist “behavior” is treated as a symbol or message that requires interpretation of its meaning, often in relation to codes, rules or norms of some sort. Psychologists, on the other hand, tend to study intellectual processes such as categorization, inference, or memory and view socially learned codes, rules, and meanings as mere content (or even as “noise”) that should be ignored or filtered out in any study of the basic elements of mental functioning.

Yet D’Andrade and Romney also made the following crucial observation, which I take to be a central tenet of cultural psychology, namely, that what you think about and with (the meaning or content of ones thinking) can be decisive for how you think and that culture and psyche make each other up. This is their key remark:

The relationship between the codes an individual learns and the intellectual processes of the individual is apparently very complex. Such processes as categorization and inference, for example, appear to be built into codes, providing the individual with a ready-made set of categories and inferences for use. However, to allow the individual to use these cognitive maps which are built into codes also demands the exercise of other complex intellectual processes. (p. 231)

They also pointed out that in any interdisciplinary research project on game-playing

behavior around the world an anthropologist “would probably come to distrust generalizations made about human behavior across all classes of games, since for him most behavior is ‘determined’ by the code in use, which varies by the game” (p. 232). I’ll return to this point later in a brief discussion of cross-cultural research in experimental economics, where behavior in the “ultimatum game” varies widely and in some counterintuitive ways (given our own culturally shaped intuitions) across cultural groups, which seems to be related to the way the game (which is itself a cultural product whose rules and meanings have been defined by the researchers) gets assimilated to local codes, rules, and meanings when transported abroad and presented to subjects in another culture. Here I simply want to note one of the lessons I took away from my 1960s reading of “Transcultural Studies in Cognition,” namely, that research designed to discover the empirically uniform features of human mentalities is likely to bracket the existence of (and hence underestimate the behavioral significance of) the local, socially learned “codes” that define social life in human groups and dismiss them as mere content, thereby ignoring one of the great sources of mental differences between the members of different code-dependent groups (cultures).

That gathering of anthropologists, psychologists and linguists in the Yucatán in Mexico in 1963 was one of many such meetings that took place in the 1960s and 1970s, premised on the article of faith that interdisciplinary conversation can be a good thing. Historical precursors and personal premonitions aside, however, I suppose I really associate the current and rather dramatic revival of cultural psychology as a vibrant and visible academic discipline with a few key academic events in the 1980s and 1990s and several nonacademic contemporary trends on the domestic and international scene.

One of those academic events was of huge import for the rebirth of an interest in higher-order units of analysis (such as culture, ethnicity, and race) among mainstream social psychologists, namely, the ongoing seminar on cultural psychology organized and run for several years in the early 1990s by Hazel Markus and Richard Nisbett at the University of Michigan. (It was a time when the reductive tendencies within psychology were apparent and social psychology was at risk of becoming a branch of

cognitive psychology, which, it has now become apparent, was itself at risk of becoming a branch of neuroscience.) During that period, interdisciplinary visitors came from all over the world to Ann Arbor, old but profound formulations in anthropology and psychology were reexamined and revived (e.g., the work of John Whiting and Irvin Child on the “custom complex” and of Harry Triandis on “individualism” and “collectivism”), and the University of Michigan and later Stanford University put themselves on the map as leading centers of research on cultural psychology, ultimately resulting in the creation of the Center for Culture and Cognition at the University of Michigan (whose vibrant voices and critical intelligences have included psychologists Phoebe Ellsworth and Shinobu Kitayama and anthropologists Lawrence Hirschfeld and Scott Atran). One should not be surprised that so many of the most active and creative social psychologists who now call themselves cultural psychologists or sociocultural psychologists (including the two editors of this volume) have ancestral connections to either the University of Michigan or Stanford University, although there are now several other leading psychology department-based centers of excellence in cultural psychology (University of California, Berkeley; University of British Columbia; University of California, Los Angeles; University of Illinois; and others). And of course there are several other centers for training and research in cultural psychology that are based in either anthropology departments (UCLA; Emory University; Duke University; University of California, San Diego) or interdisciplinary departments such as the Department for Comparative Human Development at the University of Chicago (where for nearly 70 years anthropologists and psychologists have been colleagues in the same program).

The second academic event I would mention is the Culture Theory Conference held in the spring of 1981 and subsequently published in the book *Culture Theory: Essays on Mind, Self, and Emotion* (Shweder & LeVine, 1984). Perhaps this is an all too personal and autobiographical recollection of the history of the growing interest in cultural psychology. Robert LeVine’s chapter in this volume brings us up to date and puts contemporary practitioners of cultural psychology in touch with some of their relatively recent anthropological ancestors, but it stops just short of 1984, when (at least from

my biased point of view) at least some of the current action began. It began with the publication of LeVine’s own coedited volume *Culture Theory* (which, with characteristic modesty, he never mentions). The “Culture Theory” project was an attempt to draw out the implications of a symbols- and meaning-centered or interpretive conception of culture for the study of mental functioning across groups, with special attention to certain key formulations, for example, the work of Geertz on local forms of mental functioning and culturally parochial ideas about the self. Had LeVine added just one more page to his narrative he might well have turned his attention to the conception and birth of the Social Science Research Council’s Culture Theory project, in which he played a major role and for which I was his coconspirator. It was at that conference that several anthropologists began to articulate once again (and with new ethnographic and linguistic evidence) some of the definitive and provocative ancient propositions of cultural psychology—for example, that when it comes to the study of human consciousness (including human self-consciousness) there are multiple diverse psychologies out there rather than a single psychology; and that many of those distinctive mental qualities of individuals are acquired, activated, maintained, or lost by virtue of participation in the way of life (including the linguistic life) of particular ancestral groups.

At the 1963 Romney and D’Andrade culture and cognition conference, the psychologists in attendance included Roger Brown, Jerome Kagan, William Kessen, Charles Osgood, and Fred Strodtbeck, and the anthropologists included Brent Berlin, Roy D’Andrade, Charles Frake, Dell Hymes, A. Kimball Romney, and William Sturtevant. It was the era of the cognitive revolution and “ethnoscience” was a hot topic in cultural anthropology. At the 1981 Culture Theory conference the psychologists in attendance included Jerome Bruner, Cal Izard, Martin Hoffman, Howard Gardner, Catherine Snow, and Elliot Turiel, and the anthropologists included Robbins Burling, Roy D’Andrade, Michael Fischer, Clifford Geertz, Paul Kay, Robert LeVine, Robert Levy, John Lucy, Michele Rosaldo, Bambi Scheffelin, David Schneider, Richard Shweder, Michael Silverstein, and Melford Spiro. Jürgen Habermas attended and served as the general discussant. It was an era when the cognitive revolution was no longer hegemonic and stud-

ies of self and emotion were back at center stage; one of the major aims of the conference was to critically examine the “symbolic” or “interpretative” approach to culture (as the socially inherited goals, values, and pictures of the world that are distinctive of members of different groups and made manifest in their behavioral norms), as well as the implications of that approach for research on psychological development (including research on self, emotion, moral reasoning, and language acquisition). As I recall, it was LeVine who had the prescience to recognize the potential value of Geertz’s conception of culture for the study of psychological development. At the conference we brought together anthropologists (who at the time were actively debating and trying to make sense of a Geertzian conception of culture) and psychologists (who at the time were struggling with, and resisting, the reductive and restrictive implications of the “cognitive revolution” for the study of the mental life). Many psychologists at that time were interested in going beyond the structural analysis of human perceptual and reasoning processes to the study of human wants, feelings, and values; the anthropologists believed they had something to contribute by virtue of their ethnographic research on the more revelatory and meaning-laden aspects of daily experience and the socially inherited goals, values, and pictures of reality that lead individuals to commit to a particular way of life. While there was disagreement among the conference participants about whether the “cognitive revolution” had been a blessing or a curse for the study of language, culture, and mental functioning, there was a notable level of expressed concern about the negative influence of the cognitive revolution on anthropology and psychology: concern about the apparent prestige associated with cognitive research; concern about the lack of attention to social practices and higher order units of analysis among cognitive researchers; concern about the tendency to put everything inside the head. The following fascinating exchange took place between Roy D’Andrade and Clifford Geertz (see Shweder & LeVine, 1984). This particular give-and-take raises far more issues than I can address here (for example, the direct or indirect influence of the philosophies of the early versus late Ludwig Wittgenstein on the formulations offered below; the metaphysical status of a “conceptual structure” that is not “in the head”; the way an

“interpretive approach” to culture might successfully join the study of behavior with the study of ideas), but this exchange does give a sense of how, by the early 1980s, the cognitive revolution was already “breaking up”:

ROY D’ANDRADE: When I was a graduate student, one imagined people *in* a culture; ten years later culture was all in their heads. The thing went from something out there and very large to something that got placed inside. Culture became a branch of cognitive psychology. We went from “let’s try to look at behavior and describe it” to “let’s try to look at ideas.” Now, how you were to look at ideas was a bit of a problem and some people said, “Well, look at language.” That notion, that you look at idea systems, was extremely general in the social sciences. Oh, I think, the same afternoon in 1957 you have papers by Chomsky and Miller and in anthropology, Ward Goodenough. All signal an end to the era of “Let’s look at behavior and see what they do.” Before 1957 the definition of culture was primarily a behavioral one – culture was patterns of behavior, actions, and customs. The same behavioral emphasis was there in linguistics and psychology. The idea that cognition is where it is at struck all three fields at the same time—it has a slightly different trajectory in each discipline—whether you do experiments or whether you look for intuitions or whether you talk to informants. I think it was a nice replacement. But the thing is now breaking—that force set in motion in the late fifties . . . and we each have different ideas about how it is breaking up.

CLIFFORD GEERTZ: At the same time the revolution was going on where people were putting things inside people’s heads a counterrevolution was going the other way—criticizing the whole myth of inner reality, the whole myth of private language. The one thing that anthropologists hadn’t said about culture is that it is a conceptual structure. What does it mean to say that? Take, for example, the theory of infant damnation. To know what it is you have to, first of all, conceptualize it historically and with other beliefs of this type. Then you can discuss the incidence of it, and how people got it, and how they got rid of it, and what determined all these things. But what the cultural element is, is the structure of meanings, ideas or significances that that particular religious ideology contained. The reason I am against putting things in people’s heads is that it reduces the tension between cultural analysis and psychological analysis. By psychologizing things you don’t have the kind of problematic where you can ask what is the impact of a conceptual structure or system of ideas such as the theory of infant damnation during the Ref-

ormation. What psychological effect did it have on different people in different contexts? That tends to get lost because the theory is identified as a psychological phenomenon in the first place. It's a conceptual structure—and that is what the whole depsychologizing of the concept of sense, of meaning, was all about and still is about. (pp. 7–8)

I believe it was about that time, in the early 1980s, as I prepared for the Culture Theory conference, that I began to recognize the connection between the interpretive or symbolic approach to culture and some of the tenets of the historical Romantic rebellion against the Enlightenment; and I even tried to comprehend some of the tensions that emerged at the conference in those terms (see Shweder, 1984). Even now, as I think about the intellectual foundations of cultural psychology as a discipline, I resonate to the observation by the political and moral philosopher Isaiah Berlin, in which he contrasted enlightenment figures such as Voltaire and Condorcet with Johann Herder, one of the great Romantic rebels (and a founder of cultural psychology). Berlin (1976, quoted in Gray, 1996) wrote:

For Voltaire, Diderot, Helvetius, Holbach, Condorcet, there is only one universal civilization, of which now one nation, now another, represents the richest flowering. For Herder there is a plurality of incommensurable cultures. To belong to a given community, to be connected with its members by indissoluble and impalpable ties of a common language, historical memory, habit, tradition and feeling, is a basic human need no less natural than that for food or drink or security or procreation. One nation can understand and sympathize with the institutions of another only because it knows how much its own mean to itself. Cosmopolitanism is the shedding of all that makes one most human, most oneself. (p. 122)

Perhaps that last sentence will seem shocking to some readers, especially those who live or idealize a cosmopolitan way of life. Nevertheless, the Romantic rebellion was in large part an act of intellectual resistance to the Enlightenment. It was a rejection of the Enlightenment ideal for a “modern self,” with its highly individualistic image of a fully realized human person as one who has become liberated or emancipated from all traditions, from all revelations or faith-based attachments to groups, from all commitments to received values or pictures of the world other than those that can be univer-

sally justified or grounded in logic or science. It is that “enlightened” cosmopolitan vision of the liberated individual (who is at home nowhere in particular or feels at home only when detached from all groups and loyal to none of them) that Johann Herder opposed and viewed as the shedding all that makes us most human. One trusts it is a message that many social psychologists will readily understand.

When reflecting on the contemporary psychological sciences, it is tempting to draw an analogous contrast. On the one hand, psychology aims to describe a universal psychology, and, in pursuit of that universal psychology, ends up investigating the cosmopolitan college student subject as its richest flowering and adduces an account of that psychology that is largely devoid of all mention of historical memory, local language, distinctive communal attachments, group traditions, or the parochial mental states that make us what we are. On the other hand, cultural psychology, as Herder might have envisioned it, is the investigation of those distinctive and several (or multiple) psychologies that make it possible for each of us to be and feel at home in some particular group.

Now I do not mean to suggest that any one, two, or three academic events should be fully credited with the revival of interest in cultural psychology. The organized efforts, including this monumental handbook project, to move the field forward have been many. One welcomes all of these efforts and looks forward to the day when the recent history of cultural psychology as a reemerging discipline is systematically documented. Any such history, one imagines, will surely also point to events and processes outside the academy that have created a favorable environment for the growth of a field that is so deeply concerned with questions of cultural difference. I have in mind, of course, changes in the U.S. immigration laws in the 1960s that prepared the way for increased levels of Asian, African, and South and Middle American migration; the international pendulum swing in the direction of economic globalization, which eroded national barriers to the flow of goods, information, capital, and labor (including students and scholars) all over the world; the emergence of identity politics, social justice consciousness, and affirmative action policies and their beneficial consequences for funding research or researcher training with regard to ethnic and racial minority groups; and

the various and numerous conflicts and competitions between nations and groups over the past decades (from the Japanese success in the world economy to the current war in Iraq and the tensions between Islam and Christianity in Europe) which have made it increasingly apparent that cultural differences not only are here to stay but also need to be understood for the sake of domestic and international tranquility, and for everyone's general well-being.

By now it should be apparent that I use the expression "cultural psychology" (as does Wikipedia) in a sense that is much narrower than the usage implied by the very broad reach of the preceding 33 chapters in this volume. Breadth of coverage is a good thing for a handbook, and it is a fact of life and sign of healthy intellectual activity that scholars who do comparative research on mental states and processes across code-dependent (i.e., cultural) groups do so with many different types of aims and agendas, most of which are important and legitimate. Nevertheless, not all of them are doing cultural psychology in the sense I have been describing. What is that sense?

Here I draw upon several earlier formulations in which I have tried to imagine a field of study called cultural psychology (Shweder 1990, 1991, 1993, 1999, 2003a, 2003b, and the other entries in the reference section under my name; Shweder & Sullivan, 1990). That field has a distinctive subject matter (psychological diversity, rather than psychological uniformity); it aims to reassess the uniformitarian principle of psychic unity and develop a credible theory of psychological pluralism. One does hope that it goes without saying by now that any theory of psychological pluralism would lack credibility if it staunchly denied the existence of any and all universals. That is why a credible theory of psychological pluralism, one that honors our true, deep, and significant differences, cannot and does not entail the denial of all universals. Cultural psychology presupposes many universals, including a theory of mind according to which to be a "person" is to have the capacity to initiate action; to construct a picture of the world; and to display the features of creative intelligence in the generic sense, which include the abilities to imagine the future, know things, want things, feel things, and value things (see Shweder et al., 2006). Nevertheless, as I use the expression, cultural psychology refers to the study of ethnic and cultural sources of *diversity* in emotional and

somatic functioning, self-organization, moral evaluation, social cognition, and human development.

The field also has a particular conception of the proper units of analysis for comparative research on psychological facts. It calls for the study of human "mentalities" (in the plural) as conceptualized by Johann Herder (that 18th-century Romantic German philosopher), whose central premise was that "to be a member of a group is to think and act in a certain way, in the light of particular goals, values, and pictures of the world; and to think and act so is to belong to a group" (Berlin, 1976). According to this approach to cultural psychology, the idea of "goals" includes wants, preferences, and motives of various kinds. The idea of "values" includes emotional reactions as well as "goods" and "ends" that are thought to be "preference-worthy" or morally desirable. The idea of "pictures of the world" includes local definitions and categorizations, beliefs about means-ends connections and causal connections and metaphysical and existential premises of various kinds. To describe a "mentality" (e.g., the "mentality" of Oriya Hindu Brahmins or Mandarin Chinese or liberal American middle-class anticlerical cosmopolites) is to get specific about the particular conceptual contents (the "ideas") that have actually been cognized and activated by such persons or peoples, where to "cognize" refers to any process that enables human beings to represent "ideas" (conceptual content) and to attain knowledge by deriving or computing their implications. In other words, cultural psychology is the study of the specific conceptual content that renders meaning-full behavior (or "actions") intelligible.

I have not counted how many of the chapters in this volume are prototypes or even instances of cultural psychology in that sense of the field. However, what does strike me as noteworthy is the breadth of the collection and how the expression "cultural psychology" has come to encompass so many very different types of intellectual traditions. Reading through reference sections when I first received the chapters for this volume, I had the impression that the authors were inspired by very different canonical texts and did not really share common intellectual ancestors, although for the most part, all the chapter authors have some kind of interest in research that in some sense or other is "cross-cultural." In order to be a bit more objective about the sharing

or nonsharing of canonical texts and intellectual ancestors every cited author and every cited written work in each of the chapters was entered into a database (the data analyzed were nearly complete at the time of the analysis, although a few citations that were either added or dropped during the final editorial process may have been overlooked). This made it possible to derive pairwise similarity measures for all of the chapters based on the degree of overlap either in the specific authors or in the specific works cited in their chapters and to conduct cluster and multi-dimensional scaling analyses on the co-citation or similarity structures of the chapters themselves (similarity or proximity measures were used that did not treat the joint noncitation of an author or text as a measure of sharing or similarity). It also made it possible to determine which authors and texts were the most cited and to what degree.¹

One basic fact about the citations in this volume is this: The vast majority of both cited au-

thors (approximately 77%) and cited written works (approximately 88%) are cited in some single chapter only, and not mentioned in any other chapter in the book (see Figures 34.1 and 34.2). In other words, most citations are unique; hence, the “J” shape of the curve of the distributions in the graphs is dramatic, and it reveals that, for both researchers and texts, if you are cited at all you probably are cited in only one of the chapters. Of the 3,560 written works cited herein, there is only one—Hazel Markus and Shinobu Kitayama’s (1991) *Psychological Review* article “Culture and the Self”—that is cited in even half of the chapters, and it is an outlier. Of 4,057 authors, only seven are widely cited, in the sense of being cited in at least half of the chapters. Gustav Jahoda’s useful primer on the history of theory and research on culture and mind (which I pointed to earlier) does inform the historically oriented chapter by Harry Triandis but is not mentioned in any of the other chapters.

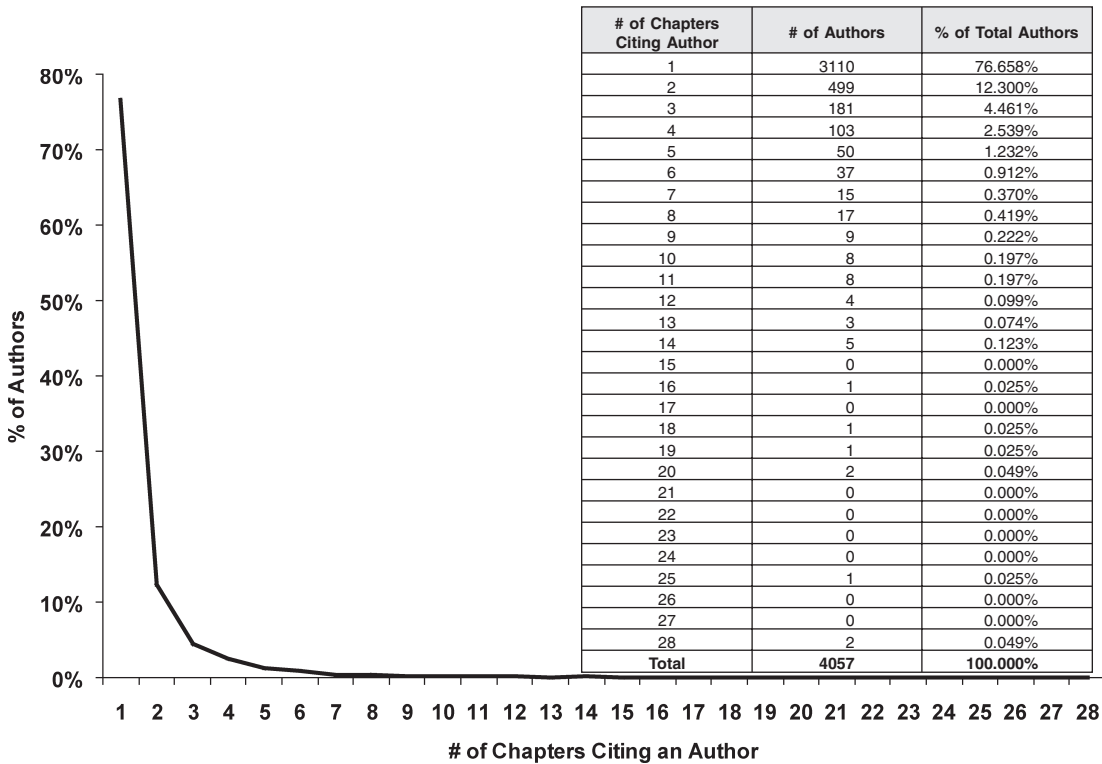

FIGURE 34.1. Citing trend of authors.

FIGURE 34.2. Citing trend of particular works.

I realize, of course, that it is hazardous to interpret the significance of this basic fact. Perhaps the relative lack of common intellectual reference points (including historical reference points) is a feature of every subfield in the social sciences. But it does give the impression that “cultural psychology,” at least in this particular usage of the expression in a *handbook of cultural psychology*, is a cover phrase for a wide range of intellectual programs and research agendas. Figure 34.3 lists the 62 most-cited authors across the chapters, where the inclusion criterion is citation in at least 8 of the preceding 33 chapters. Figure 34.4 lists the 51 most-cited written works, where the inclusion criterion is citation in at least 5 of the preceding 33 chapters. When inspecting these figures, two things seem apparent. First, the field of cultural psychology, at least among academic social psychologists, has been riding a wave associated with East/West comparisons and especially a small set of almost personality-trait-like theoretical contrasts between individualistic versus collectivist societies, independent versus interdependent selves, and analytic versus ho-

listic thinking. Secondly, the most widely cited articles are those published in a very small set of mainstream psychological journals, for example, the *Journal of Personality and Social Psychology*, *Psychological Review*, *Psychological Bulletin*, and the *American Psychologist*. Relevant articles on cultural psychology published in the journals of other disciplines (anthropology, philosophy, linguistics) are not widely cited, although three books about culture written by anthropologists (Geertz, Sperber, and Kroeber & Kluckhohn) and one written by a sociologist (by Weber) are acknowledged in at least 5 or more of the 33 preceding chapters.

Reading through this volume, the overall or general impression one gets is of the following: (1) one big idea organizing a coherent research agenda for a subset of social psychology authors interested in psychological diversity but framed very much as a debate about the scope or generality of fundamental intellectual processes and researched in a way that parallels the logic of personality-trait psychology at the level of groups and fits the format of main-

1. Give priority to the study of culturally unique psychological and behavioral phenomena or characteristics of the Chinese people.
2. Investigate both the specific content and the involved process of the phenomenon.
3. Make it a rule to begin any research with a thorough immersion into the natural, concrete details of the phenomenon to be studied.

Speaking as an anthropologist, this emphasis on starting one's research in cultural psychology with an immersion experience makes great sense and places some emphasis on field research, the observation of real-world practices and behavior (including language use), and the investigation of the native's point of view (content, meaning, and context). It also might have the effect of getting researchers in cultural psychology to rethink the dubious and hence vulnerable assumption that cultural variability can be indexed by census categories such as nationality, race, or ethnicity. Indeed it might help to free the discipline from its heavy reliance on cosmopolitan college student subjects who happen to come from different national, racial, or ethnic groups.

The advantage of taking this step can be seen in the field of experimental economics, which has for many years relied on college student subjects but has recently transported its "comparable stimuli" (its experimental games) to rural and "third-world" field settings and to the type of small-scale societies that are familiar to anthropologists. Lo and behold, they have discovered substantially greater variability in bargaining behavior in experimental game situations than previously discovered with student populations. The variability across groups that has been discovered lends itself to explanation by reference to local socially learned codes, norms, and meanings associated with social interaction in everyday life in this or that particular cultural group (Henrich et al., 2005). This research is carried forward very much in the interdisciplinary spirit of cultural psychology, with a good deal of reliance on ethnographic knowledge to build a model of a cultural mentality that helps in the interpretation of behavior in an experimental game situation (the meaning of which it is not possible for the experimenters to fully control precisely because there are cultural differences in the significance of the stimulus situation).

Consider, for example, the "ultimatum game" as defined in the experimental econom-

ics literature and described by Henrich et al. (2005):

In this game, subjects are paired, and the first player, often called the "proposer," is provisionally allotted a divisible "pie" (usually money). The proposer then offers a portion of the total pie to a second person, called the "responder." The responder, knowing both the offer and the amount of the pie, can then either accept or reject the proposer's offer. If the responder accepts, he receives the offer and the proposer gets the remainder (the pie minus the offer). If the responder rejects the offer, then neither receives anything. In either case the game ends; the two players receive their winnings and depart. Players are typically paid in cash and are anonymous to other players. . . . (p. 798)

In the comparative field-based research reported by Henrich et al. substantial amounts of money (in local currencies) were involved, and the "players" were kept anonymous to each other.

From the point of view of cultural psychology almost everything interesting about this type of experimental approach turns on understanding how the "stimulus situation," or experimental game, is understood and given meaning from the "native point of view" of members of different groups. The challenge for a cultural psychologist is to engage in the type of "thick description" of the mentality of local "game players" so as to understand precisely how and why the stimulus situation is, in fact, not the same or equivalent as it is transported from one code-dependent world to another. That is what "thick description" amounts to: specifying the local goals, values, and pictures of the world that render apparently identical stimuli (e.g., the experimenter-defined rules of the "ultimatum game") nonequivalent. Consider this possible picture of the world: Imagine a society of strangers in which all persons are motivated mainly by material rewards and hold to the premise that more is always better than less, and hence interpret the stimulus situation (the "ultimatum game") in such a way that they conclude that any proposed offer, however small, should be accepted, given the constraints of the game (because if you refuse the offer no one gets anything), leading to the shared expectation that proposers should and will offer very little and responders should and will accept it. Apparently, not even "first-world" cosmopolitan college student subjects

picture the world that way or construe the stimulus situation in those terms; the typical offer among college student subjects over many studies is around 45–50% of the original pie and college student responders typically reject low offers, even though they end up with nothing. These results have been shown to be reliable and robust across variations in the details of the experimental procedure.

More important, as one moves into rural field settings away from the “first world,” all sorts of astonishing and variable patterns of behavior emerge. This variation in “bargaining behavior” is independent of such individual characteristics of the subjects as their age, education, or wealth, and seems to be related specifically to group membership and to the particular picture of persons and social relationships shared by members of one’s group. As Henrich et al. (2005) note, “In some groups, rejection rates are extremely rare, even in the presence of low offers, while in others rejection rates are substantial, including frequent rejections of offers above 50%” (pp. 801–802). Consider, for example, the experimental game behavior of the Au and Gnao peoples of Papua New Guinea, where many “proposers” offered more than 50% of the available currency and many of these offers were turned down by the “responder,” leaving both “players” with nothing.

What thick description of goals, values, and pictures of the world can help us comprehend what the stimulus situation actually meant to these subjects? Henrich et al. offer the following explanation:

The rejection of seemingly generous offers, of more than half, may have a parallel in the culture of status-seeking through gift-giving found in Au and Gnao villages, and throughout Melanesia. In these societies, accepting gifts, even unsolicited ones, implies a strong obligation to reciprocate at some future time. Unrepaid debts accumulate, and place the received in a subordinate status. Further, the giver may demand repayment at times, or in forms (political alliances), not to the receiver’s liking—but the receiver is still strongly obliged to respond. As a consequence, excessively large gifts, especially unsolicited ones, will be refused. (p. 811)

The main (and perhaps obvious) point to be made here is that there are many different pictures of the world or cultural mentalities that might be brought to the table when “playing an

experimental game” (of course, that very way of describing the interaction or event is itself a discretionary and not mandatory way of understanding the stimulus situation), and “thick description” is a way of rendering behavior intelligible in terms of local and socially shared meanings.

I think something like that form of explanation—thick description of local meanings—is pretty much what D’Andrade and Romney (1964) had in mind when they wrote:

The relationship between the codes an individual learns and the intellectual processes of the individual is apparently very complex. Such processes as categorization and inference, for example, appear to be built into codes, providing the individual with a ready-made set of categories and inferences for use. (p. 231)

Indeed, that may be one of the primary reasons for cultural group based variations in bargaining behavior in the “ultimatum game.”

Although I have raised some questions about heterogeneity of coverage, the publication of this volume is a monumental achievement and marks a new stage in the revival of the field. Back in 1964 it was not obvious that in the coming decades so many mainstream social psychologists would embrace the notion of cross-cultural research and run with it in so many fascinating directions, or that so many would become suspicious of strong claims about psychic unity and seriously entertain the possibility that mentalities are not uniform around the world. Nor, might I add in conclusion, was it obvious back then that work in experimental economics would simultaneously force us to recognize the importance of ethnographic fieldwork with diverse groups, deepen our appreciation of the psychological significance of social learned cultural codes, and lend support to the central notion of cultural psychology that culture and psyche make each other up.

NOTE

1. I am most grateful to Michele Wittels and Jacob Hickman for assisting me in these analyses. Any detailed presentations and discussion of the taxonomic structure of the Handbook chapters based on their cocitation patterns will have to wait for another occasion. Here in this commentary I just want to make a few brief observations about the breadth of this volume and raise a question or two about the future of the field.

ACKNOWLEDGMENT

I wish to thank Jacob Hickman and Michele Wittels for their research assistance in the preparation of this commentary and the Carnegie Foundation of New York and the Russell Sage Foundation for their support of my research in cultural psychology.

CHAPTER 35

A Psychological Perspective

Cultural Psychology—Past, Present, and Future

RICHARD E. NISBETT

People who are unaware of the history of cultural psychology are surprised to learn that the founder of experimental psychology, Wilhelm Wundt, was also a cultural psychologist. He believed that one could not understand behavior by just looking at what people were doing in laboratories. One also had to know history and culture. Kurt Lewin, the founder of the field of experimental social psychology, was also a student of collectives of all sorts. He actually wrote one important ethnography comparing Germany and the United States. And there was always a fundamental concern with history and culture and collective issues on the part of the Soviet psychologists, notably Vygotsky and Luria. Through at least the 1950s, plenty of psychologists—especially social psychologists—were concerned with societal and collective and cultural issues.

But a very dramatic shift away from concern with culture occurred roughly in the mid-60s. I have two theories about why this happened. I think it was partly because culture in the 1940s and 1950s was studied in the context of what was called the “culture and personality movement.” Unfortunately,

this movement operated with the two predominant theories in the behavioral sciences, and these were not well suited for studying culture. One of these, Freudian theory, is perfectly good for some things, including, for example, the theory of “preperception” in attention. But Freudian theory just is not very good for studying culture. Cultures do not differ from one another because of when they do their toilet training or how they resolve their Oedipus complexes. The other orientation that guided research was learning theory. When applied to human behavior, the theory was rarely used in an explanatory or predictive, as opposed to a purely circular, fashion. Why do people do what they do? Well, because they are being reinforced for it. And how do we know that they are being reinforced for it? Well, because they are doing it. As Robert Abelson pointed out, social psychology, which is the fountainhead of contemporary cultural psychology, is the only field of psychology that was never behaviorized. It was always clear to social psychologists that cognitive structures in people’s heads were doing the work, although it was

not until the late 1960s that people began to get some idea of what those cognitive structures might look like.

Another important factor in the shift away from collective phenomena is that, roughly in the early 1960s, it began to be clear that social psychologists were doing science. When dissonance research was starting to be done, it was very exciting to people to realize that one could do things that were replicable, surprising, and incontrovertible. The social psychologists of the 1960s were able to demonstrate interesting and surprising phenomena in the laboratory, and they had good theories as to why the phenomena occurred. Dissonance theory was followed by attribution theory, which was similar in many ways in that the experiments were difficult to refute and the theories were well grounded. But studies of collective phenomena, including culture, just did not have that ring of science. The methods were sufficiently weak that if a piece of research turned up something that seemed implausible, one was not inclined to trust the research over a prior opinion. Given a choice between science and journalism, the field stampeded toward science.

Still another reason for the movement away from collective phenomena may have to do with the center of gravity of psychology shifting so completely from Europe to North America. And we North Americans are so individualistic in our orientation that that stance carried over into the discipline, including our understanding of how to look at things and what things are interesting to look at. Social psychology began to become the study of the individual—or, to be more precise, of the individual's thoughts about the world. There is real discomfort on the part of Europeans with what is called "methodological individualism." I have an acquaintance, a German political scientist, who tells me that when he goes back to Germany for a conference, it is like going into a room where there is sufficient oxygen. He feels very weighed down by the necessity to communicate with his American colleagues, who tend to insist that all phenomena are rightly understood at the individual level rather than, at least sometimes, having to go to some higher, broader level of analysis. This is something I'm very sympathetic with now, but I would not really have understood the complaint not so long ago.

So, for about 30 years, I'd say Harry Triandis, Michael Bond, John Berry, Michael Cole, and only a few others were among the

small cadre of people doing cultural psychology in a way that spoke to the scientist. Like many people, I was paying some attention to what they were saying. But they did not really influence what most social psychologists thought they should be doing. My own attitude toward their work, and the work of the Soviet cultural psychologists, was that there was probably some truth to what they were saying, but the claims of cultural differences were probably exaggerated and at any rate were peripheral to my concerns.

What really got the attention of the field—certainly of those of us working in attribution research and convinced of the universality of the fundamental attribution error—was Joan Miller's (1984) dissertation. I think our convictions about universality were far from being unexamined assumptions. We could have given excellent reasons for why the fundamental attribution error had to be universal and equally strong in all cultures. The primary reason for this for me, at least, was that I believed that the error was at base a perceptual phenomenon. And I still think that is essentially correct. It is just that it would have been hard to guess how much perception is influenced by culture. Miller's research made it abundantly clear that the fundamental attribution error was much more prevalent for some peoples than for others. The work was so well done and so convincing that I experienced a certain exhilaration when I first read the paper, though basically I was not pleased to see the results. I suppose I was like the wife of the Bishop of Worcester after Darwin's theory of evolution was explained to her: "My dear, let us hope that it is not true, but if it is, let us pray that it will not become generally known."

Miller's work did not immediately spawn other research in cultural psychology, but after 7 or 8 years psychologists all over North America suddenly began thinking about cultural differences, and within short order began producing the sort of work that fills this volume. Personally, I was quite surprised to see so many people working in the field so quickly. As Daniel Dennett has said, you think you are original, and then you realize you've just been floating on the Zeitgeist. And the Zeitgeist has just continued to shift in the direction of cultural psychology. More and more people want to know whether the phenomena they are been investigating look the same in cultures different from their own.

Why did the shift take place, and why does it remain largely a North American phenomenon? One reason I think is that it suddenly dawned on psychologists that not everybody is North American. This had been obvious to Europeans. There was once an article by a Frenchman on American social psychology, with an amusing title, something like “The Social Psychology of the Nice Guy” (whom he regarded with the disdain the French reserve for Americans). Perhaps the flattening of the world had something to do with the emergence of cultural psychology. The world started shrinking and there was increasing immigration to the United States and to Canada. There was competition from Japan, which obviously did all kinds of things drastically differently from the way we did. Suddenly American academics realized they could not ignore the other 96% of the world.

But I think a major ingredient in the move toward cultural research has to do with our realization that the strong inference techniques that we have honed, experimental techniques in particular, can be applied to cultural phenomena. We stopped being interested in collective questions in part because we found that we could make so much more progress with questions at the individual level. But then, starting about 15 years ago or so, people began realizing that the methodology developed over the preceding 20–30 years was adequate to speak in a thoroughly scientific way to collective questions. And once we started doing it, and realizing that the inferences were really as tight as elsewhere in psychology, it was a big thrill.

As this volume shows, what we have now is an absolute flood of research. And I do not think it is like any prior movement in social psychology. It is substantially bigger and qualitatively different from dissonance or attribution, or person memory or judgment and decision making. It is not a topic that in 6 or 7 years will no longer interest people. It is a new way of doing business. I do not think we can (or, at any rate, should) make assertions about human behavior anymore without having in the back of our minds, “How would this play through in other cultures?”

Another striking thing is that psychology is going to be reshaped by ideas from outside the Western tradition. East Asians are particularly well placed to play a creative role because of the very different nature of their societies and the capacity to draw on intellectual traditions

that are thousands of years old. In one case, by the way, a social science field has already been totally transformed by East Asians—primatology. Thirty years ago, Western primatologists could not see anything larger than a dyadic relationship among primates. But Japanese primatologists insisted that the relationships are extremely complex. There are coalitions that involve many individuals and that shift over time. The reaction to this on the part of Western primatologists was derision at first. *Nature* magazine published a condescending, early critique of Japanese primatology that maintained the culture of the Japanese had colored their view of the relationships among primates. Indeed. Now the entire field shares the Japanese assumptions about the nature and complexity of primate relationships.

As to the future, I do not pretend to know what will happen, but there are several things I would like to see happen. Some of them have to do with my own confusions.

First, should we think about culture as traits? For some kinds of behaviors, that analogy seems very powerful and largely correct, at least to a first approximation. Individualism versus collectivism, or independence versus interdependence, clearly can be thought of very much like a trait dimension. In fact, Harry Triandis (1995) has argued, successfully in my view, that there are traits at the level of individuals within a culture that mimic those poles, namely, idiocentrism and allocentrism. The same thing is true of dominance behavior, aggressive behavior, and extraversion. It makes sense to think of cultures as being relatively extraverted or relatively introverted. The Finns like to say that the difference between a Finnish introvert and a Finnish extravert is that the introvert looks at his shoes when he talks to you and the extravert looks at your shoes. And I think it is fair to say that Americans as a group compared to, say, the English or the Japanese, are rather extraverted.

On the other hand, sometimes it makes more sense to look at culture as a chronic situation, or set of situations. Lee Ross has a nice anecdote that provides a helpful way to think about the way material aspects of situations both reflect and sustain cultures. He spent 1 or 2 weeks at an academic institution in Spain. Hanging around with the faculty and graduate students he had a wonderful time, going out to tapas bars, having wine and conversations late at night, and walking along the streets to the

parks. It was all marvelous and Lee found he fit right in. He thought to himself, "I'd like to bring as much of this as possible to Stanford. I'm going to shift Palo Alto culture, or at least my part of it in the social psychology program, toward Spanish academic culture." But it turns out there are some problems with that. For starters, there are not any tapas bars in Palo Alto. And a person can't go from one place to any other place in Palo Alto without getting into a car. And that sort of breaks the rhythm: "You take the Volkswagen and I'll take the SUV, and we'll get everybody downtown." You're not in the Mediterranean any more if you're having to do that. Beyond that is the fact that one tapas bar would not do the trick. The institution is tapas bar *hopping*, not just plopping down in a tapas bar. Work and sleep schedules are sufficiently different in Palo Alto than those in the Mediterranean that even a cluster of tapas bars would not really sustain the culture. Climate would also conspire. It can get cold at night in Palo Alto, and then there is the rainy season to contend with, and so on. Lee did not get very far with his desire to create a Spanish academic culture at Stanford.

So actual physical setups determine what kinds of cultural attributes are possible. Hazel Markus and I, in our first cultural psychology seminar, had students write a brief ethnography. One of the most insightful, and sad, was by Susan Cross, who grew up in Houston. She recounted the profound change in the nature of social life that was produced by the introduction of the air conditioner. Previously a great deal of social life was oriented around the porch, where people would sit in the evening to cool off and invite people strolling along the sidewalk to come up for a visit. But the advent of the air conditioner changed all that. No longer was it necessary to sit on the porch to cool off, and no longer was there a motive to stroll the sidewalks during an evening. Social life withered into the connectionless accumulations of people in malls and Astrodomes and bowlers bowling alone.

A second set of questions concerns the triggering of cultural phenomena, notably, how long it takes to adopt the social and cognitive habits of a host culture and the degree to which priming of certain orientations can mimic the effects of culture. The "framed line" findings of Kitayama, Duffy, Kawamura, and Larson (2003) are extremely thought provoking, in that they suggest that living in a new environ-

ment even for a relatively brief amount of time can produce a shift in perception that is influenced by culture, namely, attention to a focal object versus attention to the field. Americans living in Japan are moved substantially toward the Japanese pattern of greater ability to reproduce the length of a line relative to its surrounding square compared to ability to reproduce the absolute length of the line. Japanese living in America are nearly identical to Americans in their tendency to be equally adept at both productions. Of course it is possible that those Japanese living in the United States were just self-selected because they were very American from the start. And maybe the Americans who went to Japan were pretty Japanese from the start. But it seems equally likely that something is happening chronically to people in the two cultures that makes them have certain kinds of perceptual orientations. One possibility is that the society is different with respect to some important social practices. The practices direct attention differently, either specifically to objects and one's goals in relation to them in the case of the West, or toward the social environment and, consequently, the environment more generally in the case of the East (Markus & Kitayama, 1991). The Kitayama et al. (2003) findings suggest that if we reverse the chronic orientation for a modest period of time, we may reverse the perceptual habits as well.

But it may be possible to produce "cultural" shifts with far less exposure to culture-relevant stimuli. There is evidence that even brief exposures to stimuli that trigger interdependent versus independent orientations (e.g., having people think about the ways in which they are similar to others vs. the ways in which they are different from others) have effects on social cognition and even on attentional processes (Gardner, Gabriel, & Lee, 1999; Haberstroh, Kühnen, Oyserman, & Schwarz, 2000; Hong, Morris, Chiu, & Benet-Martinez, 2000; Kühnen, Hannover, & Schubert, 2001; Kühnen & Oyserman, 2002; Trafimow, Triandis, & Goto, 1991). Because everyone has moments when attention is directed toward individual objects (including themselves), and moments when their attention is directed toward contexts (including other people), there can be acute analogues to chronic cultural states. Everyone can be relatively interdependent or independent. Consequently everyone can be deflected toward objects and goals or toward looking more broadly at the environment.

The priming studies raise another important question for the future: What is modifiable in the short term and what is not? Can we turn anybody into a member of another culture just by priming procedures? It is astonishing (to me, at least) that just circling first-person plural pronouns (*we, us, ourselves*) in a paragraph makes people less capable of solving embedded figures problems than they are after circling first-person plural pronouns (*I, me, mine*). Hannah Chua, Julie Boland, and I (Chua, Boland, & Nisbett, 2005) have found that in the first second of looking at a picture Americans focus on the object for an average of 600 milliseconds compared to 40 milliseconds for Chinese—a finding that helps to explain why Americans are more likely to attribute events to objects, and Asians to attribute to contexts. Would the pronoun prime affect whether a person's eye movements focus more on backgrounds rather than objects? Would the pronoun prime make people more likely to reason in dialectical ways (Peng & Nisbett, 1999)? Less likely to apply logic to everyday problems (Norenzayan, Smith, Kim, & Nisbett, 2002)? More likely to organize objects and events on the basis of relationships rather than categories (Chiu, 1972; Ji, Zhang, & Nisbett, 2004)? Less able to realize that they should be surprised by some unusual fact they have just been told (Choi, 1998; Choi & Nisbett, 2000)? Obtaining the latter effects would suggest that perceptual differences are more closely tied to cognitive ones than is currently assumed to be the case, and that the two are linked more tightly to culture than is assumed. Most importantly, such results would suggest that independence and interdependence serve as major coordinates organizing a wide variety of mental functions. And if priming procedures could produce such broad and general components of different cultures, what other sorts of cultural differences can be primed by similar manipulations?

There is evidence that environments in which people live habitually, as well as the environments to which they are exposed acutely, can affect the nature of perception. There are myriad sights on the East Asian street, whereas American environments are relatively simple. Yuri Miyamoto, Taka Masuda, and I (Miyamoto, Nisbett, & Masuda, 2006) have found that Japanese urban environments are just much more complex than American ones. Whereas objects stand out against relatively empty backgrounds in American environ-

ments, everything is context in Japanese environments. There are three important consequences:

1. Americans tend to see objects when they look at a scene; Japanese tend to see backgrounds and relationships among objects.
2. Both Americans and Japanese, when looking at American scenes, tend to see objects; and both groups, when looking at Japanese scenes, tend to see backgrounds and relationships.
3. Even brief exposure to Japanese scenes makes both Japanese and Americans more likely subsequently to focus on contexts rather than objects as compared to brief exposure to American scenes.

Here, again, is an instance of producing culture-like differences on an acute timescale that resemble those produced by chronic conditions.

Some cultural differences are not like chronic situations and not like temporary states, and not like personality traits, but something like what Harry Triandis refers to as cultural syndromes and others refer to as culture complexes. In some Arab cultures, for example, every man knows that it is an incredible infraction to look directly at his wife's face. They just know that—it is not as if this is an individual difference we could sensibly examine in their culture, let alone in ours. People in New Jersey just do not differ in the degree to which they see the world in that respect; no Jerseyites feel that way.

I can tell two anecdotes about furniture that each tapping into culture complexes that are impenetrable to me. Michael Morris tells about his sister, who worked for many years in Japan. Early on she went to some friends' apartment and saw a desk that they had. She said, "Gee, that's a lovely desk." The next day, to her mortification, the desk was delivered to her home, and every month its former owners would come back and polish it for her. Contrast that with the wealthy English gentleman who invited an American to his home. The American made the apparently ghastly mistake of complimenting the man's dining room chairs. "My gosh, those are gorgeous Chippendale chairs." And the English gentleman threw him out of his house. "Damn fellow thinks he can praise my chairs." It would probably take me hours to learn to give a coherent verbal account of

what is going on in these furniture episodes, and years to understand them in some deep intuitive way.

Then there are culture complexes I have worked on myself, including the culture of honor I researched with Dov Cohen (Cohen, Nisbett, Bowdle, & Schwarz, 1996; Nisbett & Cohen, 1996). There is a syndrome of believing that you have to protect yourself, your home, and your family without the aid of the law, that violence, or the threat of it, is a necessary response to an insult, and that you have to be terribly polite to people yet frank and direct when necessary to avoid conflict. This is not best thought of as a personality variable. It is a syndrome, and in a culture like that you are going to participate in that syndrome to one degree or another. But there is not a comparable syndrome in other cultures, so there cannot be individual differences in it. The pieces are not united in the same way in other cultures. Cohen actually has evidence of this in recent work showing that various attitudes and behaviors hang together in the South in ways that they do not in the North (see, e.g., Leung & Cohen, 2006; Cohen, Vandello, Puente, & Rantilla, 1999). Most importantly, the sorts of things that predict honor-related violence are quite different in the North than in the South. Endorsement of honor-related aggression in the North is associated with social disruption and anomie—higher divorce rates, more moving around, and so on. But endorsement of honor-related aggression in the South is associated with social cohesion and organization—lower divorce rates, more stable residence patterns, and so on (Cohen, 1998). Violence in the North, in other words, is in part the result of social pathology. Violence in the South is learned at Mother's knee.

Or take a cultural syndrome that is even more clearly a conglomeration rather than a trait, namely, the Calvinist Protestant ethic complex. There are people who think they have got to work hard all the time and be thrifty, that they should never buy a car better than a Chevrolet because that would be too showy, that they should not enjoy eating or any of the other pleasures of the flesh too much, or incur obligations to people, that they should not get too emotionally close to people, and that everybody has a calling or should have—not just a job, but a calling. Well, it would be preposterous to talk about this dog's breakfast of attributes as a personality trait. Instead, it is some

kind of syndrome or culture complex. People in a given Calvinist subculture may differ to one degree or another in the extent to which they participate in the syndrome: It may “take” to different degrees in different people, but it would be absurd to think that the attributes would hang together for people not part of such a culture. Actually, there is reason to doubt that the attributes of such complexes correlate all that well even in cultures that have them. Cohen (2006, Chapter 8, this volume) did not find a coherent, underlying factor of Jewish religious observance. To one person, being Jewish means doing X; to another, being Jewish means doing Y; and for yet another person it means doing Z. Cohen (2006) looked at eight religious behaviors—keeping kosher, fasting on Yom Kippur, having a seder, lighting Shabbat candles, and so on. After excluding the Orthodox individuals whose very strong ideology requires following all the practices, and the purely secular, who follow none, they found that the correlation between following any two practices ranged from .1 to .2.

So when is it best to think about some cultural fact in one way and when in another? I believe we will be making a lot of progress on this question in the near future.

I believe that some culture complexes will turn out to be “unprimable.” I doubt that there is a simple prime that can make a Northern, suburban Jewish boy behave like a Southern, rural Baptist kid by insulting him. You could get the Northerner mad, even mad enough to take a swing at somebody else, but I doubt whether you could get him to think that he was *obligated* to inflict physical harm to maintain his reputation for toughness. Still less would you be able to get him to think that the *only appropriate* way to respond to an insult is through physical violence. I also doubt that you could prime a Spanish Catholic to think that she must really discover her calling by getting her to think about luxury goods.

How long do you have to live in a culture before you think habitually like a native? Before your socioemotional reactions are like those of a native? As an example of my own bias, I suspect some aspects of cognition, and perhaps habitual aspects of attention, can change at a fairly late point to a fairly marked degree, perhaps in late adolescence or even early adulthood. (And David Liu, Jan Leu, and I have some preliminary data indicating that this is actually the case for Asian immigrants to Amer-

ica.) But like many developmental psychologists, I suspect socioemotional attributes cannot change much past late childhood. I left Texas at 17, and I used to think of myself as a standard-issue liberal pacifist, but after I started studying the culture of honor I realized that I was very much imbued with that culture. You can take the boy off the ranch, but you can't take the ranch out of the boy. Similarly, I used to think I was a completely fallen-away Methodist, but reading Weber was a revelation to me. I am a Calvinist almost to the core: I could not live with myself if I did not think I had a true calling and, at least until I grew fat and sleek-headed under the influence of my adored, sybaritic spouse, was compulsively thrifty and luxury-avoidant.

Still other questions for the future have to do with what is universal after all. We have an interesting case history of universality lost and near-universality regained for cognitive dissonance. It looked for quite a while as if we would be unable to find dissonance effects in Asia in either the forced compliance or the free choice paradigm (Heine & Lehman, 1997). It is now clear that we can get dissonance effects with Asians; it is just that very different conditions are required to elicit them than is the case for Westerners. Westerners worry about whether they are competent decision makers, thus showing dissonance effects even when they are by themselves. Asians are more worried about what other people will think about their choices and show dissonance reduction effects only when they are primed to think about other people while they are making their decisions (Kitayama, Snibbe, Markus, & Suzuki, 2004). The same is true for the fundamental attribution error; that is to say, it is alive and well in the East, just more easily avoided there than in the West because of greater Eastern sensitivity to situational factors (Choi & Nisbett, 1998; Norenzayan & Nisbett, 2000). We do not have to give up either of these staples of social psychology—though we are going to have to think about them in very different ways than in the past.

In fact, I think we will have to think about all psychological phenomena—down to the level of allegedly cognitively impenetrable perception—in very different ways. We can no longer assume that everybody thinks, feels, and sees in the same way—even when they are placed in what appears to the observer to be identical situations.

PART VIII

EPILOGUE

CHAPTER 36

Cultural Psychology

This Stanza and the Next

DOV COHEN
SHINOBU KITAYAMA

“Universalism without the uniformity” may be a good way to describe cultural psychology (see Shweder, Chapter 34, this volume). And perhaps it is a decent way to describe this handbook as well. The chapters in this volume have a great deal in common, but they also illustrate the many ways one can be a cultural psychologist.

As a final word, we briefly try to sum up some themes that emerged in this book and what they may point us toward in the future. One can readily identify four themes that give some unity to the emerging field. Cultural psychologists tend to regard culture as a dynamic system of practices and meanings (a definitional tenet of the field); they regard content and process of the mind as inseparable (a theoretical tenet); and they tend to rely heavily on “thick experimentation” (a methodological tenet). In addition, cultural psychologists tend to regard Westernization as only one rather limited social force that is influencing the non-Western world today. Each of these points can be traced back to a variety of different intellectual traditions such as experimental psychology, social psychology, and anthropology

among others. Yet in combination they establish cultural psychology as a relatively unified field that is well positioned to grow.

1. A definitional tenet of cultural psychology says that culture is composed of a rich network of practices, meanings, and attendant psychological habits and experiences. In this respect, cultural psychology is somewhat different from older, more traditional approaches to culture in psychology, which tended to focus on abstract values or national character.

Cultural psychologists believe, to use Einstein’s famous phrase, that culture does not work through “spooky action at a distance.” It works through the quotidian—the way we tell stories, eat, speak, cook, socialize, make love, act, sleep, remember, perceive, comport our bodies and so on (see, e.g., Brewer & Yuki, Chapter 12; Chiu, Leung, & Kwan, Chapter 27; Fiske & Fiske, Chapter 11; Hatfield, Rapson, & Martel, Chapter 31; Mesquita & Leu, Chapter 30; J. Miller, Chapter 19; P. Miller, Fung, & Koven, Chapter 24; Rozin, Chapter 16; Sanchez-Burks & Lee, Chapter 14; Schooler, Chapter 15; Wang & Ross, Chap-

ter 26, all this volume; see also Kim, 2002; Konner, 2002; Shweder, 1993; Tsai, Louie, Chen, & Uchida, 2007). It gets instantiated in the everyday practices of our world. The point might seem obvious at first. However, this way of thinking would make it clear that culture is not separable from the mind. Instead, it is a dynamic system of which a mind is part. Moreover, the idea of culture as a dynamic system is central to the *methodology* of cultural psychologists who tend to focus on processes that *re-create* culture in the everyday—rather than, say, on the measurement of abstract values, personality traits, or macro-level indicators (see Markus & Hamedani, Chapter 1 this volume).

This re-creation is an active process that people engage in. Culture is not the dead weight of history, carried forward through inertia (Moore, 1966). It is remade daily in the quotidian.

2. A theoretical tenet of the field holds that processes of the mind are inseparable from the content that makes up the mind. The “old” division in psychology was between *how* human beings thought and *what* they thought about. The first was the really interesting stuff that was the purview of “real” psychologists. The latter was . . . not. Even if one initially accepted this dubious and territorial belief, cultural psychology has redrawn the map and has shown how the *what* and the *how* are fundamentally inseparable. The work on independence versus interdependence and holistic versus analytic cognition makes this clear (Oyserman & Lee, Chapter 10; Kitayama, Duffy, & Uchida, Chapter 6; Norenzayan, Choi, & Peng, Chapter 23; Nisbett, Chapter 35, all this volume; also Cohen, Hoshino-Browne, & Leung, 2007; Leung & Cohen, in press), but the point about content and process being inseparable is also implicit in other places as well (see, e.g., Marsella & Yamada, Chapter 33, this volume, on psychopathology, and Chiu et al., Chapter 27, on language). *What* we think affects *how* we think, and *how* we think affects *what* we think.

3. A methodological corner stone of the field lies in what one may call “thick experimentation.” As Shweder (Chapter 34, this volume) notes, the discovery of meaning is central to the mission of cultural psychology. Fieldwork that produced “thick description” was the path to the discovery of meaning. However, with some notable exceptions (see, e.g., J.

Miller, Chapter 19; P. Miller et al., Chapter 24; Morelli & Rothbaum, Chapter 20, all this volume), the field has been a little thin on “thick description.” Most cultural psychologists (at least, most in this book) are still *psychologists*, and most have retained their general disciplinary bias toward more quantitative analysis.

Meaning is still central, however, and one of the advances has been the development of a type of “thick experimentation” that uses the tools of traditional psychology to discern meaning and even provide nuance and texture. Research programs on the meaning of choice and on the role of self-enhancement and self-criticism in the United States and Japan are two such examples (Kitayama et al., Chapter 6; Heine, Chapter 29; Markus & Hamedani, Chapter 1, all this volume; Hoshino-Browne, et al., 2005; Snibbe & Markus, 2005; Kitayama & Markus, 1999; Heine, Lehman, Markus, & Kitayama, 1999; see also Mendoza-Denton & Mischel, Chapter 7, this volume, for an individual differences approach that highlights the psychological meanings of events).

“Science,” it has been said, “is the search for better and better control conditions.” In this light, researchers have focused on the situations *when* an effect occurs to understand *why* an effect occurs. Rozin’s elaborate program of research on disgust, eating, and contamination is another example of how controlled experiments can tease apart the meaning of stimuli and reveal the laws of sympathetic magic that transform a basic disgust reaction into a culturally elaborated emotion of moral significance (see Rozin, Chapter 16, this volume; Rozin, Haidt, & McCauley, 2000).

Of course, to set appropriate control conditions requires substantial ethnographic knowledge informed by an insider’s point of view (Geertz, 1973). This is the case because cultural meaning systems must be understood from the logic of the inside, and not from the vantage point of some presumed “universal cultural logic.” Thus, for example, it requires thinking like an insider to understand why a belief in fatalism or predestination can result in (a) economic languor in one culture and (b) the strict, austere Calvinist work ethic in another (Sanchez-Burks & Lee, Chapter 14; Heine, Chapter 29; J. Miller, Chapter 19, all this volume; see also Bond et al., 2004). Thus we believe that work in cultural psychology should be informed by both thorough, first-hand knowledge about the culture at hand

(e.g., ethnography) and careful experimentation designed to elucidate the underlying meaning systems.

4. Cultural psychologists are skeptical of the notion of uniform Westernization. Contemporary American rhetoric regards Western values as the ideal that all rational people would and will aspire to (once they become sufficiently educated, wealthy, or cured of their delusions). It professes an almost magical belief that drinking American soda pop, wearing “American” jeans (actually made in a “third-world” country), and having a TV satellite dish are enough to transform people into Americans (Huntington, 1996). And it regards every blip of convergence or similarity in public opinion as proof positive that a new era (an era of modern Western values) has arrived.

Cultural psychologists regard all these claims with suspicion. The belief in an inevitable Westernization (a) ignores the way cultures often adapt each others’ customs for their own ends, (b) seems contradicted by the empirical record of the long *duree* (Braudel, 1980), and (c) assumes dubiously that Western values are universal values.

With respect to the first point, globalization may indeed internationalize some customs. However, these customs are often adapted to local practices (Hong, Wan, No, & Chiu, Chapter 13, this volume), and non-Western peoples are no less adept than Westerners at collectively reinventing the meaning of what they import from elsewhere. Because culture is composed of a system of meanings and practices that are interlocking and often redundant with one another (see Schooler, Chapter 15, this volume), new practices, tools, and ideas from elsewhere are more likely to be assimilated than accommodated.

Second, empirically, technological change and its accompanying affluence and affordance of possibilities seems to have led to more cultural divergence rather than less across the long *duree*. Braudel (1980) asks us to engage in a thought experiment: “Turn the problem around . . . and note the unity of earlier times . . . Should the historian turn toward those past ages. . . , he will perceive as many astonishing resemblances and analogous rhythms working independently thousands of miles apart. [Ming China] was assuredly closer to the France of the Valois than the China of Mao Tse-tung is to the France of the Fifth Republic” (p. 213).

Finally—and this is mostly a matter of faith—cultural diversity seems to be an inevitable part of the human condition, because cultures must necessarily make trade-offs between different values (Shweder, 2000). And whereas cultures may all universally regard values such as autonomy, purity, community, mercy, justice, and social order as good things, cultures will differ in (a) how they conceive of these values as being implemented and (b) how much they are willing to trade-off one value for another when these values inevitably conflict (hence Shweder’s [2000, p. 164] “universalism without the uniformity”). We may all agree that “vice is virtue to excess” or “everything in moderation,” but what is “excess” and what is “moderation”?

These four tenets of cultural psychology seem to make up the “family resemblance” of work here: (1) Culture works through the quotidian, rather than through “spooky action at a distance”; (2) culture is both content and process and the two are fundamentally linked; (3) “thick experimentation” and observation can be used for the important task of uncovering meaning and understanding cultural logics from the inside; and (4) non-Western people are not simply Westerners “in disguise”—their values must be taken seriously and have an enduring appeal that may resist Westernization. There may be more core tenets. There may be fewer (all are, after all, *empirical* claims and are thus subject to revision). Nevertheless, this handful seems a reasonable starting point.

The chapters of this volume make it obvious that these four tenets can comprise no more than a “family resemblance” (rather than a strict definition) because there is a fair amount of variation in how researchers go about studying cultural psychology. However, where there is deviation from these four tenets also shows us where the field has room to grow. Below, we list three areas that may merit further exploration.

1. Individuals are active participants in their culture (see point 1, above), and that means they are free to contest, reject, or react against the culture they are in. Cultural psychology has tended to focus on the re-creation of cultural patterns, so it has tended to focus on stability rather than change and prototypical behavior rather than variation (cf. Newson, Richerson, & Boyd, Chapter 18, this volume). There has

been some research examining individual differences (see, e.g., work summarized in Cohen, Chapter 8; Tov & Diener, Chapter 28; Medin, Unsworth, & Hirschfeld, Chapter 25; Mendoza-Denton & Mischel, Chapter 7; Nisbett, Chapter 35, all this volume; Leung & Cohen, 2007; Fu et al., in press; Kitayama, Markus, Matsumoto, & Norasakkunkit, 1997). However, for the most part, cultural psychologists have focused on prototypes rather than patterns of within-culture variability.

As Konner (Chapter 4, this volume; see also LeVine, 2001, Chapter 2, this volume; Triandis, Chapter 3, this volume) notes, a single prototype focus was one of the factors that doomed studies of “national character” and one faction of the old “culture and personality” movement: “Individual variation . . . is great in every known culture. . . . At best there is perhaps a ‘modal personality,’ shared by a substantial minority of a culture’s members . . . and in any case a culture must derive its distinctiveness from the particular mutual articulation of its various personality types, and the opportunities it provides for their expression, rather than from fundamental tendencies shared by a majority—a sort of symphony orchestra model of culture and personality, in which each culture provides a series of scores” (Konner, Chapter 4, this volume, p. 79). A study of *patterns* of variation rather than *prototypes* provides one important way for the field to grow theoretically and avoid degenerating into caricature.

2. The study of culture and evolution can be integrated. As has been observed, what begins as heresy ends as common sense. No longer is E. O. Wilson vilified for the suggestion that evolution may have shaped human psychology. Cultural psychologists not only need to make their peace with evolution but also must integrate this knowledge into our understanding of culture. As a whole, the field has yet to do so, but it is starting to confront the issue seriously (see Konner, 2002, Chapter 4, this volume; Atran, Chapter 17; Chiao & Ambady, Chapter 9; Cole & Hatano, Chapter 5; Levenson, Soto, & Pole, Chapter 32; Li, Chapter 21; Newson et al., Chapter 18, all this volume; Norenzayan & Heine, 2005). Similarly, biological research represents another way we can enrich our field, provided we do serious work and not simply “ooh and ah” whenever we find out that some psychological process is reflected in—surprise!—the brain (Chiao & Ambady,

Chapter 9, this volume; see also discussions by Harmon-Jones & Winkielman, 2007, and the special issue of the *Journal of Personality and Social Psychology* edited by Harmon-Jones & Devine, October 2003).

3. There is still plenty of unexplored territory in terms of populations and phenomena to be studied (see Rozin, Chapter 16, and Shweder, Chapter 34, both this volume). Psychology is more than just the study of upper-middle-class white Americans, and cultural psychology is more than just the study of upper-middle-class white Americans and Asians. By far, these are the two dominant groups that cultural psychologists have examined (cf. Sternberg, Chapter 22, and Hatfield et al., Chapter 31, both this volume). However, we must take our own critique of mainstream psychology seriously and expand the samples we study. Our job is *not* to take on the Sisyphian task of cataloging the world’s cultures. But obviously, if we take seriously our own argument that human psychology shapes and is shaped by culture, then there is still plenty about human psychology that has yet to be discovered and *cannot* be discovered without expanding the range of populations we study.

Expanding our samples and the phenomena we study is necessary for our theories and for understanding some of the real issues that present themselves in the world today. These include issues such as the vexing problem of race in America; the friction between secularism and religion in the West and the frictions between different religions in the West and Middle East; the increased immigration that will occur as ageing “first-world” countries try to recruit productive young workers from abroad; environmental problems that will require cooperation from both developed and developing countries; the persistent poverty of underdeveloped nations; and so on. As the salience of these issues grows, avenues of research in cultural psychology will expand.

In summary, we hope that the work in this handbook marks a beginning—or, more properly, a renewal of psychology’s interest in culture (Markus & Hamedani, Chapter 1; Nisbett, Chapter 35; Shweder, Chapter 34; Triandis, Chapter 3, all this volume). We hope this current generation of research can add something to the long line of work that has come before it. Mark Twain is often (and perhaps apocryphally) credited with saying, “His-

tory does not repeat itself, but it does rhyme.” Our hope is that this handbook can add another stanza to this long history of the study of culture and psychology.

Subject Index

- Abacus expertise
 cultural practices amplification, 127–130
 neuronal changes, 128
- Absolutist view of culture and psychology, 66
- Abstract verb phrases
 vs. concrete verb phrases, 684
 in outgroup behavior descriptions, 684
- Academic achievement
 and life satisfaction, 702
 socioeconomic status effects, 377
- Accessibility effects, and priming, 263
- Accountability, in moral reasoning, 486–487
- Acculturation
 definition, 65
 developmental perspective, 329–330
 psychological adjustment, 331–332
 and psychopathology, 804
- Aché culture, childhood model, 86–87
- Achievement motivation, and religion, 168, 715–718
- Acoustic startle
 autonomic effects, 787, 788
 cultural effects susceptibility, 788
- Acquiescence bias, 141, 166, 219, 706
- Action readiness, 742–746
 cultural context link, 745–746
 cultural themes, 743
 in emotional experience, 736, 742–746
 and general somatic activity, 743
 and happiness, 743–744
 Northern vs. Southern U.S. men, 745
 in shame reactions, 744
- Action regulation, 139–153
 and health and well-being, 152–153
 independent vs. interdependent cultures, 142–153
 motivational consequences, 151–152
 principle of, 142–143
 and social relations, 139–145
 style of, emotional consequences, 151
- Activity theory. *See* Cultural–historical activity theory
- Adaptation
 and cultural diversity, 458–459
 environmental context, 64
 myth of, 208
 religion theory, 422–426
- Adjustment style
 and depression, 749
 East Asians vs. North Americans, 145–147, 748
 ideal affect link, 748
 vs. influence style, 145–147, 748
- Adult Attachment Interview, 518
- Adultery. *See* Sexual infidelity
- Advertisements, East–West differences, 164, 222, 326, 684, 728
- Advertising, research samples, 215
- Affordances. *See* Cultural affordances
- African Americans
 baseline autonomic physiology, 786
 emotion production studies, 787
 facial expression, 784
 fantasy narratives, 600, 610
 individualism vs. collectivism effect sizes, 258–260
 schizophrenic symptoms, 809
 storytelling, young children, 600
 stress reactions, physiology, 786
- Africans
 collectivism vs. individualism, 258–259
 context-related intellectual abilities, 557–559
 intelligence conception, 551–553
- Agemate relationships, 288
